THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXIX. NEW YORK, SATURDAY, JULY 4, 1896. NO. 1.

ORIGINAL ARTICLES.

THE REPORT OF THE AMERICAN PEDIATRIC SOCIETY'S COLLECTIVE INVESTIGATION INTO THE USE OF ANTITOXIN IN THE TREATMENT OF DIPHTHERIA IN PRIVATE PRACTICE.[1]

THIS subject was chosen by the officers of the Society for its eighth annual meeting, with the belief that a large amount of valuable experience not otherwise available, might in this way be reached and collated. It was also believed that a more trustworthy estimate of the value of the serum treatment of diphtheria might thus be obtained than by statistics taken from hospital practice. There are very few hospitals in America that receive diphtheria patients, and the conditions under which patients are admitted to hospitals and the surroundings while there, are so different from those of private practice, that the measure of success in hospital cases cannot be taken as an index of the results which have been obtained upon this side of the Atlantic with the new treatment.

In order, therefore, to obtain an expression of opinion from American physicians as to the serum treatment, after what had been, with most of them, their first year's experience, a circular letter was prepared and issued by the Committee early in April. This was distributed through the members of the Society as widely as could be done during the time allowed. An attempt was made to reach as many physicians as possible who had had experience with the remedy.

The first surprise of the Committee was in learning how very widely the serum treatment had been employed, especially in the Eastern and mid-Western States. With more time, the number of cases collected might easily have been doubled and perhaps trebled; but enough reports have come in to enable one to see what opinion was held on the 1st of May, 1896, by American physicians who have used this remedy.

The circular letter asked for information upon the following points: Age; previous condition; duration of disease when the first injection was made; the number of injections; the extent of the membrane—tonsils, nose, pharynx, and larynx; whether or not the diagnosis was confirmed by culture; complications or sequelæ, viz., pneumonia, nephritis, sepsis, paralysis; the result; and remarks, including other treatment employed, the preparation of antitoxin used, and general impression drawn from the cases.

Reports were returned from 615 different physicians, with 3628 cases. Of these, 244 cases have been excluded from our statistical tables. These were cases in which the disease was said to have been confined to the tonsils and the diagnosis not confirmed by culture, and therefore open to question. A few cases were reported in such doubtful terms as to leave the diagnosis uncertain. The figures herewith given are therefore made up from cases in which the diagnosis was confirmed by culture (embracing about two-thirds of the whole number) and others giving pretty clear evidence of diphtheria, either in the fact that they had been contracted from other undoubted cases, or where the membrane had invaded other parts besides the tonsils, such as the palate, pharynx, nose, or larynx. It is possible that among the latter we have admitted some streptococcus cases, but the number of such is certainly very small.

There are left then of these cases, 3384 for analysis. These have been observed in the practice of 613 physicians from 114 cities and towns, in 15 different States, the District of Columbia, and the Dominion of Canada.

In the general opinion of the reporters the type of diphtheria during the past year has not differed materially from that seen in previous years, so that it has been average diphtheria which has been treated. If there is any difference in the severity of the cases included in these reports from those of average diphtheria, it is that they embrace a rather larger proportion of very bad cases than are usually brought together in statistics. The cases, according to the extent of the membrane, are grouped as follows: In 593 the tonsils alone were involved. In 1397 the tonsils and pharynx, the tonsils and nose, the pharynx and nose, or all three were affected. In 1256 cases the larynx was affected either alone or with the tonsils, pharynx, and nose, one or all. In many instances,

[1] Reported at the Eighth Annual Meeting held at Montreal, Canada, May 26, 1896.

the statement is made by the reporters that the serum was resorted to only when the condition of the patient had become alarmingly worse under ordinary methods of treatment. This is shown by the unusually large number of cases in which injections were made late in the disease. Again, many physicians being as yet in some dread of the unfavorable effects of the serum have hesitated to use it in mild cases and have given it only in those which from the onset gave evidence of being of a severe type. The expense of the serum has unquestionably deterred many from employing it in mild cases. These facts, it is believed, will more than outweigh the bias of any antitoxin enthusiasts by including many mild cases which would have recovered under any treatment. It will, however, be remembered, that tonsillar cases not confirmed by culture have not been included.

Only two reports embracing a series of over one hundred cases have been received, most of the observers having sent in from five to twenty cases, although there are many reports of single cases, particularly of single fatal ones.

In addition to this material which has come in response to the circular, there have been placed at the disposal of the Committee, by the courtesy of Dr. H. M. Biggs, 942 cases treated in their homes in the tenements of New York. Of these, 856 were injected by the corps of inspectors of the New York Health Board, upon the request of the attending physician, and 86 others were treated by physicians receiving free antitoxin from the Health Board. In the first group the diagnosis of diphtheria was confirmed by culture in every case, and in all of the latter except 26; in these the diagnosis rested upon extensive membranous deposits or laryngeal invasion. The cases of the New York Health Board were of a more than ordinarily severe type, 485, or more than fifty per cent. of these being reported as being in bad condition at the time of injection; to mild cases the inspectors were not often called. Further, an unusually large number of them (thirty-eight per cent.) were injected on or after the fourth day of the disease. In 182 of these cases only the tonsils were affected; in 466 the tonsils with the pharynx or nose, the pharynx and nose, or all three; in 294 the larynx was invaded either with or without disease of the tonsils, nose, or pharynx.

Through the courtesy of Dr. Biggs the committee is able to include also a partial report upon 1468 cases from Chicago, treated in their homes in that city by a corps of inspectors of the Health Department. It was the custom in Chicago to send an inspector to every tenement-house case reported, and to administer the serum unless it was refused by the parents. These cases were therefore treated much earlier and the results were correspondingly better than were obtained in New York, although the serum used was the same in both cities, viz., that of the New York Health Board.

THE RESULT AS INFLUENCED BY THE TIME OF INJECTION.

In Table I are given the results obtained in these three different groups of cases, classified according to the day on which they received the first injection of serum antitoxin.

TABLE I.—DAY OF INJECTION AND RESULT.

	Injected on 1st Day.			Injected on 2nd Day.			Injected on 3rd Day.			Injected on 4th Day.			Injected on or after 5th Day.			Day of Injection Unknown.			Totals.		
	Cases.	Deaths.	Mortality per cent.	Cases.	Deaths.	Mortality per cent.	Cases.	Deaths.	Mortality per cent.	Cases.	Deaths.	Mortality per cent.	Cases.	Deaths.	Mortality per cent.	Cases.	Deaths.	Mortality per cent.	Cases.	Deaths.	Mortality per cent.
The Committee's Report,	764	38	4.9	1065	89	8.3	620	79	12.7	336	77	22.9	390	152	38.9	215	15	7.0	3384	450	13.0
New York Health Board,	126	11	8.7	215	26	12.0	228	37	16.6	153	32	20.9	203	59	29.0	17	4	23.5	942	169	17.8
Chicago Health Board,	106	0	0	336	5	1.5	660	18	2.7	269	38	14.1	97	33	34.0	0	0	0	1468	94	6.4
Totals, - - -	996	49	4.9	1616	120	7.4	1508	134	8.8	758	147	20.7	690	244	35.3	232	19	8.2	5794	713	12.3

The grand total gives 5794 cases, with 713 deaths, or a mortality of 12.3 per cent., including every case returned; but the reports show that 218 cases were moribund at the time of injection or died within twenty-four hours of the first injection. Should these be excluded there would remain 5576 cases (in which the serum may be said to have had a chance) with a mortality of 8.8 per cent.

Of the 4120 cases injected during the first

three days there were 303 deaths—a mortality of 7.3 per cent., including every case returned. If from these we deduct the cases which were moribund at the time of injection, or which died within twenty-four hours, we have 4013 cases, with a mortality of 4.8 per cent. Behring's original claim, that if cases were injected on the first or second day the mortality would not be 5 per cent., is more than substantiated by these figures. The good results obtained in third-day injections were a great surprise to your Committee. But after three days have passed the mortality rises rapidly, and does not differ materially from ordinary diphtheria statistics. Our figures emphasize the statement so often made, that relatively little benefit is seen from antitoxin after three days; however, it must be said that striking improvement has in some cases been seen even when the serum has been injected as late as the fifth or sixth day. The duration of the disease, therefore, is no contraindication to its use.

THE INFLUENCE OF BACTERIOLOGICAL DIAGNOSIS UPON THE STATISTICS.

This is shown in Table II.

TABLE II.—DIAGNOSIS CONFIRMED BY BACTERIOLOGICAL EXAMINATION.

	Cases.	Deaths.	Mortality.
Committee's Report,	2453	302	12.3 per cent.
New York Board of Health,	916	160	16.9 "
Chicago " "	1468	94	6.4 "
Totals, - -	4837	556	11.4 "
(Excluding 145 cases which were moribund or which died in twenty-four hours), - - -			8.7 "

DIAGNOSIS FROM CLINICAL EVIDENCE ONLY.

	Cases.	Deaths.	Mortality.
Committee's Report,	931	148	15.7 "

Totals, - -	957	157	16.3 "
(Excluding 72 cases either moribund or dying in twenty-four hours), - - - - - -			9.6 "

In the cases in which the diagnosis was not confirmed by a bacteriological examination the mortality is thus 5 per cent. higher than in the bacteriological cases. The difference is to be explained by two facts: first, as already stated, that we have excluded from our reports all tonsillar cases (and hence most of the very mild ones) not confirmed by bacteriological examinations; and secondly, by the fact that this group of cases comprises those treated in the country where physicians have hesitated to use antitoxin unless the type of the disease was a grave one, and where also a large proportion of the injections were made later than in the cities. However, should we leave out the moribund cases, the mortality is but 9.5 per cent., which differs but slightly from the cases confirmed by bacteriological diagnosis.

In our subsequent statistics we shall consider together all the cases bacteriologically confirmed and otherwise, as the statistics are not materially altered by this grouping.

THE RESULTS AS MODIFIED BY THE AGE OF THE PATIENTS.

Unfortunately the ages have not been furnished in the report of the Chicago cases, and we have therefore only the cases reported to the Committee and those from the New York Board of Health for analysis. In Table III is shown the mortality of the different ages grouped separately.

The highest mortality is seen as in all reports to be in the cases under two years, but including all those returned even those that were moribund when injected, the death rate was but 23.3 per cent. (21.7 per cent. of the Committee's cases), while if we exclude cases moribund when injected or dying within the first twenty-four hours, it falls to 19.2 per cent.

After the second year there is noticed a steady

decline in mortality up to adult life. In many of the reports previously published the statement has been made that no striking improvement in results was observed in adults cases treated by the serum. Our figures strongly contradict this opinion. Of 359 cases over fifteen years old, which were returned, there were but thirteen deaths. That the reader may judge for himself how far antitoxin is to be held responsible for the result, a brief summary of these thirteen cases is appended.

CASE I.—Fifteen years old; injected on the fourth day; membrane covering tonsils and pharynx; profoundly septic, sinking rapidly when injected; died in two hours. "My only death in seventeen cases." (Jones, Gloucester, Mass.)]

CASE II.—Forty-four years old; injected on the fourth day; membrane on the tonsils and pharynx; in bad condition; died three hours after injection. The tonsils had been previously incised, the early diagnosis having been quinsy.

CASE III.—Thirty-one years old; injected on the sixth day; membrane on the tonsils, nose, pharynx, and larynx; intubation; sepsis; in bad condition; lived eight hours after injection.

CASE IV.—Thirty-five years old; injected on the fifth day; membrane on the pharynx and nose (?); in bad condition; septic; died in twelve hours.

CASE V.—Sixty years old; in bad condition; had serious mitral regurgitation; injected on the fourth day; membrane covering tonsils, pharynx, and larynx; died from heart failure on following day.

CASE VI.—Sixty years old; "kidney trouble for years;" injected on the third day; very extensive membrane, covering tonsils, pharynx, and nose; profound sepsis; in bad condition; died suddenly on the day after injection.

CASE VII.—Seventeen years old; in bad condition; convalescing from measles; enormous adenopathy; profound sepsis; exceedingly high temperature; membrane covering tonsils and nose; injected at the end of forty-eight hours; three injections, temporary improvement after each one; duration of life not given.

CASE VIII.—Fifteen years old; in bad condition; injected on the ninth day; membrane covering tonsils, nose, pharynx, and larynx; no operation; enormous infiltration of the tissues of the neck; nephritis; sepsis; lived four days and died of sepsis.

CASE IX.—Twenty years old; injected on the third day; membrane upon the tonsils, nose, pharynx, and larynx; "a stubborn patient, who got up before he was allowed, and died suddenly after it."

CASE X.—Twenty-five years old; injected on the fifth day; membrane covering both tonsils, entire pharynx, and completely occluding nose; nephritis and sepsis; throat cleared off entirely; died suddenly on the fourteenth day from cardiac paralysis.

CASE XI.—Nineteen years old; injected on the fifth day; membrane upon the tonsils and pharynx; profound sepsis; duration of life unknown.

CASE XII.—Twenty-two years old; injected on the fourth day; membrane on the tonsils and gums; sepsis; died on the sixth day.

CASE XIII.—The well-known Brooklyn case, reported in 1895. Girl, sixteen years old, who died suddenly, ten minutes after injection.

Such are the adult cases, which antitoxin failed to cure. Four of them were moribund at the time of injection, no one of them living over twelve hours. Two, both sixty years old, were already crippled by previous organic disease, one of the heart, and the other of the kidneys. In the measles case there was undoubted evidence of streptococcus septicemia. Only two of the cases were injected as early as the third day; three of them on the fifth day, and one on the ninth day. Omitting the four moribund cases, the mortality of 355 adult cases treated with the serum is 2.5 per cent.

PARALYSIS.

Reliable data upon this point and those hereafter to be mentioned are to be had only from the 3384 reports returned to the Committee. Of these, paralytic sequelæ appeared in 328 cases—9.7 per cent. Of the 2934 cases which recovered, paralysis was present in 276, or 9.4 per cent. Of the 450 cases which died, paralysis was noted in 52, or 11.4 per cent.

The variety of the paralysis and the date of injection is shown in Table IV.

Observations of some of the individual cases are interesting, particularly those of cardiac paralysis. It is twice stated that the child had gotten up and walked out of the house, where it was found dead. Twice death occurred after sitting up suddenly; once, on jumping from one bed into another. One patient of twenty years got up, contrary to orders, and died soon afterward. Another patient was apparently well, until he indulged in a large quantity of cake and candy, soon after which cardiac symptoms developed, and he died shortly. One case was that of a woman, sixty years old, who had serious organic cardiac disease.

It is difficult from these statistics to state what protective power the serum may have over the nerve-cells and fibers. Apparently this is not great, unless the injections are made early in the disease, and even then in severe cases the amount of damage done to these tissues in twenty-four hours may be very great, even irreparable. Time

is not the only element in estimating the effect of the diphtheria toxins.

Great discrepancy exists in the statements made regarding the frequency of paralytic sequelæ after diphtheria. In a series of 1000 cases reported by Lennox Browne, paralytic sequelæ were present in 14 per cent. In 2448 cases by Sanné, paralysis was noted in 11 per cent. In the series of cases here reported, the difference is slightly in favor of the antitoxin treatment, but paralysis is certainly frequent enough to show how extremely susceptible the nervous elements are to the diphtheria toxins. One thing is quite striking from a study of these cases, and that is the proportion that have died from late cardiac paralysis. That very many of them would undoubtedly have succumbed earlier in the disease from suffocation (laryngeal cases) or diphtheritic toxemia, had the serum not been employed, is beyond question. Although the serum is able to rescue even many such desperate cases, it cannot overcome the effects of the toxins upon the cells, which have occurred before it was injected.

SEPSIS.

Sepsis is stated to have been present in 362 of the 3384 cases, or 10.7 per cent. It was present in 145, or 33 per cent. of the fatal cases. Some explanation is necessary for a correct appreciation of these figures. The majority of the reporters, it is plain from their remarks, have not distinguished between diphtheritic toxemia and streptococcus sepsis. The former is certainly meant in the great majority of the cases. There is a very small proportion in which there is evidence of streptococcus sepsis. The six cases complicating measles and the five complicating scarlet fever, however, should possibly be included among this list.

NEPHRITIS.

The statements on this point are quite unsatisfactory. The reports state that nephritis was present 350 times, or in ten per cent. of the cases. On the one hand, it must be stated that the diagnosis of nephritis rests, in many cases, simply upon the presence of albumin in the urine; but, on the other hand, it is true that in a large number of the cases—more than half—no examination of the urine is recorded as having been made, so that it is impossible to state with anything like approximate accuracy, the frequency of nephritis in these cases. Of the 450 fatal cases, the presence of nephritis is mentioned without qualification or explanation in thirty-nine cases, these being usually put down also as septic, dying in the acute stage of the disease. There are fifteen fatal cases, however, in which the renal disease was stated as the cause of death. In no less than nine the nephritis occurred late in the disease, usually during the second or third week. In these fifteen cases the evidence of severe nephritis was conclusive, such symptoms being present as dropsy, suppression of urine, with coma or convulsions.

BRONCHO-PNEUMONIA.

Broncho-pneumonia is stated to have been present in 193 of the 3384 cases, or 5.9 per cent., a remarkably small proportion when compared with hospital statistics. Among the patients that

[1] Cases of heart failure occurring at the height of the disease have not been included here; although they are mentioned among the cases of cardiac paralysis in the table of fatal cases.

recovered, broncho-pneumonia was noted 114 times, or in 3.8 per cent.; among the fatal cases, 79 times, or in 17.5 per cent.; but in only about one-half of these was the pneumonia the cause of death. Of these, 37 were laryngeal cases, operated upon late; 10 were septic cases, and the pulmonary disease was coincident with the height of the diphtheritic process. In 7, pneumonia was independent of both the above conditions, occurring late in the disease in all but two.

LARYNGEAL CASES.

Of the 3384 cases reported to the Committee, larynx is stated to have been involved in 1256 cases or 37.5 per cent. This proportion is somewhat higher than is usual, and is partly explained by the fact that several physicians have sent in the reports only of their laryngeal cases. These laryngeal cases occurred in the practice of 379 physicians.

In 691, or a little more than one-half the number, no operation was done, and in this group there were 128 deaths. In 48 of them laryngeal obstruction was responsible for the fatal issue, operation being refused by the parents, or no reason for its being neglected having been given. In the eighty remaining fatal cases the patients died of other complications, and not from the laryngeal disease.

In the 563 cases, therefore, or 16.9 per cent. of the whole number, there was clinical evidence that the larynx was involved, and yet recovery took place without operation. In many of these cases the symptoms of stenosis were severe, and yet disappeared after injection without intubation. No one feature of the cases of diphtheria treated by antitoxin has excited more surprise among the physicians who have reported them, than the prompt arrest, by the timely administration of the serum, of membrane which was rapidly spreading downward below the larynx. Such expressions abound in the reports as "wonderful," "marvelous," "prepared to do intubation, but at my next visit the patient was so much better it was unnecessary," "in all my experience with diphtheria have never seen anything like it before," "no unprejudiced mind could see such effects and not be convinced of the value of the serum," etc.

In establishing the value of the serum, nothing has been so convincing as the ability of antitoxin, properly administered, to check the rapid spreading of membrane downward in the respiratory tract, as is attested by the observations of more than 350 physicians who have sent in reports.

Turning now to the operative cases we find the same remarkable effects of the antitoxin noticeable. Operations were done in 565 cases, or in 16.7 per cent. of the entire number reported. Intubation was performed 533 times with 138 deaths, or a mortality of 25.9 per cent. In the above are included nine cases in which a secondary tracheotomy was done, with seven deaths. In 32 tracheotomy only was done with 12 deaths, a mortality of 37.4 per cent. Of the 565 operative cases, 66 were either moribund at the time of operation, or died within twenty-four hours after injection. Should these be deducted, there remain 499 cases operated upon by intubation or tracheotomy, with 84 deaths, a mortality of 16.9 per cent.

Of the 2819 cases not operated upon, there were 312 deaths, a mortality of 11.3 per cent. Deducting the moribund cases, or those dying within twenty-four hours after injection, the total mortality of all non-operative cases was 9.12 per cent.

Let us compare the results of intubation in cases in which the serum was used, with those obtained with this operation before the serum was introduced. Of 5546 intubation cases in the practice of 242 physicians, collected by McNaughton and Maddren (1892) the mortality was 69.5 per cent. Since that time statistics have improved materially by the general use (in and about New York, at least) of calomel fumigations. With this addition, the best results published (those of Brown) showed in 279 cases a mortality of 51.6 per cent.

Let us put beside the cases of McNaughton and Maddren the 533 intubations with antitoxin, with 25.9 per cent. mortality. With Brown's personal cases let us compare those of the fourteen observers who have reported to the Committee ten or more intubation operations in cases injected with serum. These comprise 280 cases with 65 deaths, a mortality of 23.2 per cent. In both comparisons the mortality without the serum is more than twice as great as in the cases in which serum was used.

The reports of some individual observers concerning intubation with the serum are interesting:

Neff, New York: 27 operations, with 27 recoveries.

Rosenthal, Philadelphia: 18 operations, with 16 recoveries.

Booker, Baltimore: 17 operations, with 17 recoveries, including one aged ten months, and one seven and a half months.

Seward, New York: 8 operations, with 8 recoveries.

McNaughton, Brooklyn: "In my last 72 operations without serum, mortality 66.6 per cent.; in my first 72 operations with serum, mortality 33.3 per cent."

O'Dwyer, New York: "In my last one hundred intubations, first 70, without serum, mortality 73 per cent.; last 30, with serum, mortality 33.3 per cent.

But even these figures do not adequately express the benefit of antitoxin in laryngeal cases. Witness the fact that over one-half the laryngeal cases did not require operation at all. Formerly ten per cent. of recoveries was the record for laryngeal cases not operated upon. Surely, if it does nothing else, the serum saves at least double the number of cases of laryngeal diphtheria that has been saved by any other method of treatment.

The great preponderance of intubation over tracheotomy operations shows how much more highly the profession in this country esteems the former operation.

A STUDY OF THE FATAL CASES.

Of the 450 fatal cases in the Committee's Report, 229, or one-half, received their first injection of the serum on or after the fourth day of the disease, and 152, or over one-third of these, on or after the fifth day.

There were 58 cases in which it was stated that the child was moribund at the time of injection, the serum being administered without the slightest expectation of benefit, but at the earnest solicitation of the parents.

There remain 350 cases in which the cause of death could be accurately determined by the reports. These died from the following causes, the most important cause being placed first:

Sepsis (*including diphtheritic toxemia*) was the cause of death in 105 cases; of which sixteen had nephritis, four were intubated or tracheotomized, two were laryngeal cases not operated upon, four had paralysis, one had pneumonia, and in one the fatal sepsis was attributed to a traumatic condition of the left knee.

Cardiac paralysis was the cause of death in 53 cases. Under this head are included cases of sudden heart failure occurring at the height of the disease (twenty-one in number) as well as those more commonly designated as heart paralysis, where death occurred suddenly after the throat cleared off. Of the latter there were thirty-two examples; four of these cases had throat paralysis, nineteen were septic, eight had nephritis, five were intubated, and one tracheotomized.

Broncho-pneumonia was put down as the cause of death in 54 cases. In 37 of these it followed laryngeal diphtheria; of these 22 were intubated, and four tracheotomized; two had nephritis; nine were septic. Broncho-pneumonia and sepsis was the cause of death in 10 cases, of which three had nephritis and one general paralysis. Broncho-pneumonia caused death in seven cases, apart from sepsis or laryngeal diphtheria; of these only one had nephritis; one died from heart failure; and in five pneumonia came on late in the disease.

Laryngeal diphtheria without operation caused death in 48 cases. In some of these the operation was refused by the parent, in others it was neglected by the physician, the patients dying of asphyxia; 3 of these cases had nephritis, 4 were septic, 2 had pneumonia, and 1 had sepsis and nephritis.

Diphtheritic tracheitis or bronchitis caused death in 11 cases; all of these were intubated, and in 2 there was evidence of the existence of membrane in the bronchi before operation. There were 33 other cases in which death followed laryngeal diphtheria without the supervention of pneumonia. It is highly probable that in some of these death was due to membranous tracheitis or bronchitis. All of them were operated upon; 10 were septic, 2 had paralysis, and 1 had nephritis.

Sudden obstruction of the intubation tube was the cause of death in 3 other laryngeal cases.

The tube was coughed up in 3 cases, fatal asphyxia occurring before the physician could be summoned.

Died on the table during tracheotomy, 1 case.

Nephritis was the cause of death in 15 cases; 7 of these were septic, and 3 had been intubated.

General Paralysis was the cause of death in 5 cases; in all probably the pneumogastric was involved.

Paralysis of the respiratory muscles produced death in 1 case, 1 of laryngeal diphtheria, which was intubated, and was complicated by broncho-pneumonia.

Measles associated with diphtheria produced death in six cases; 5 of these were laryngeal and were intubated; in 2 there was pneumonia, and in 2 sepsis. Diphtheria developed during the height of the measles, or immediately followed it.

Scarlet fever with diphtheria was the cause of death in 6 cases; in 3 of these there was broncho-pneumonia, nephritis, and sepsis; in 2 scarlet fever preceded diphtheria, and in 1 of these there was sepsis with gangrene of the tonsils. In

the sixth case the patient died of scarlet fever, which developed during convalescence from the diphtheria.

Gangrene of the cervical glands or cellular tissue of the neck was the cause of death in 2 cases associated with profound general sepsis.

Endocarditis caused death in 1 case, nineteen days after the diphtheria.

Diphtheritic inflammation of the tracheal wound with sepsis caused death in 1 case.

General tuberculosis, five weeks after diphtheria, was assigned as the cause of death in 1 case.

Exhaustion was the cause of death in 3 cases, 1 a protracted case; another complicated by pneumonia and sepsis; 1 by nephritis.

Convulsions was the cause of death in 3 cases apart from disease of the kidneys. In 1, the well-known Brooklyn case, the girl died ten minutes after the injection, in another, twenty-four hours after injection, in the third, the particulars were not given.

Meningitis was assigned as the cause of death in 1 case.

THE KIND OF ANTITOXIN USED.

They are given in the order of frequency with which they have been used. First, the serum prepared by the New York Board of Health; second, Behring's; third, Gibier's;[1] fourth, Mulford's; fifth, Aronson's; sixth, Roux's. In addition a large number of cases are reported as having been treated by the serum prepared by the health boards of different cities—Brooklyn, Newark, Rochester, Pittsburg, etc. The largest number of cases have been treated by the serum prepared by the New York Health Board, a very large number by Behring's serum, all others being relatively in small numbers.

Dosage and number of injections. In the great majority of cases but one injection is reported. In very severe ones two and three have been given. The largest amount is in a case by Weimer (Chicago) who gave eighteen injections of Behring's serum to a laryngeal case in a child thirteen years old. Another instance of ten injections is reported with no unfavorable symptoms.

As a rule the dosage has been smaller in antitoxin units than is now considered advisable, particularly in many of the laryngeal cases and others injected later than the second day.

[1] It is worthy of note that in the tests made by the State Board of Health of Massachusetts, published under date of April 6, 1896, this serum was found far below the standard as labeled upon the bottle; thus a package marked to contain 2500 units, by test was found to contain less than 700. All the other varieties of serum tested were found essentially up to the standard.

CASES INJECTED REASONABLY EARLY (DURING THE FIRST THREE DAYS) IN WHICH ANTITOXIN IS SAID TO HAVE PRODUCED NO EFFECT, THE DISEASE ENDING FATALLY.

These cases are nineteen in number. Brief reports are introduced that the reader may judge to what degree they may be regarded as a test of the serum treatment. In our statistical tables all of them have been included among the fatal cases.

In Cases I and II the cultures were reported negative. Case I, by Gallagher, New York: Child, eighteen months old; septic; although no eruption was present, the reporter was "inclined, on reflection, to regard this case as one of scarlatinal sore throat."

CASE II, by Potter, Buffalo: Male, fourteen months old; two cultures made, but no Loeffler bacilli found; membrane in the nose and pharynx. Injected on the third day, one dose of Behring's serum No. 1. No improvement; death from sepsis. "Probably pseudo-diphtheria" (I. H. P.).

In Cases III to IX no cultures were made.

CASE III, by Tefft, New Rochelle: Seven years old; injected after eighteen hours' illness; two injections of Behring's No. 2 serum; membrane on the tonsils, pharynx, and nose; no effect observed from injections; patient dying on the third day.

CASE IV, by Tefft: Male, four years old; membrane on the tonsils and pharynx; injected after thirty-six hours' illness with Behring's No. 2; died on the third day; no noticeable effect from the injection.

CASE V, by Tefft: Six years old; membrane on the tonsils, nose, and pharynx; septic; injected after thirty-six hours' illness; three injections of Behring's No. 2. "Saw no effect from the injections, the disease going steadily on to a fatal termination."

CASE VI, by Cameron, Montreal: Two and a half years old; fifty hours ill; membrane on the tonsils, nose, and pharynx; septic; no improvement noticed, and child died twenty hours after injection.

CASE VII, by Baker, Newtonville, Mass.: three years old; laryngeal diphtheria; injected on the third day 10 cc. Roux's serum; cyanosis; intubation; temperature 103° F., and continued high until death in eighteen hours after operation; injections had no effect.

CASE VIII, by Anderson, New York: Three years old; injected after three hours' illness; membrane on the tonsils, nose, and pharynx; one injection New York Health Board antitoxin. "A case of malignant diphtheria, full duration twenty-four hours."

CASE IX., by McLain, Washington: Four years old; twelve hours sick; membrane on the pharynx and larynx; two injections; no operation; first injection early in the morning, the other early in

the afternoon; died the same day; no change in the condition; antitoxin had no apparent effect.

In Cases X to XIII diphtheria complicated measles, all reported by W. T. Alexander, New York. Disease confined to the larynx in all; in three the stenosis developed during measles, and in one while the patient was convalescing from measles; diagnosis confirmed by culture in every case, and in all intubation performed. Antitoxin seemed to have no effect, the cases going on to a fatal termination; all received their injections within twenty-four hours after the laryngeal symptoms appeared.

In three cases—XIV to XVI—the type of the disease was malignant from the outset.

CASE XIV., by Lloyd, Philadelphia: Fifteen months old; injected after thirty-six hours' illness; diagnosis confirmed by culture; membrane covered the tonsils, pharynx, nose, and larynx; intubation; sepsis; death on the fifth day. Although antitoxin was used as promptly as possible no perceptible effect noticed. One injection, Behring's No. 3, was given.

CASE XV, by Wert, Mount Vernon, N. Y.: Eighteen months old; injected on the third day; diagnosis confirmed by culture; membrane on the tonsils and pharynx. "Very intense type of the disease." Antitoxin could not be procured before the third day; Gibier's serum used. "Died suddenly in apparent convulsions about ten hours after injection; urine not examined; very little passed."

CASE XVI, by Ingraham: Six years old; membrane covered the tonsils, pharynx, and larynx; diagnosis confirmed by culture; pneumonia present; condition very bad; injected after two and a half days' illness; three injections of Behring's serum; no benefit noticed.

CASE XVII, by Johnson, Buffalo: Three years old; twelve hours ill; case septic from the start; membrane on the tonsils, pharynx, and larynx; diagnosis confirmed by culture. "Antitoxin apparently had very little effect."

CASE XVIII, by Baker, Newtonville, Mass.: Two and a half years old; twenty hours ill; disease confined to larynx; diagnosis confirmed by culture; one injection of Gibier's serum; intubation. "Was doing well a few minutes before death when child got up in its crib, changed color and died almost immediately." Death attributed to "sudden heart failure; found no obstruction of the tube."

CASE XIX, by Story, Washington: Five years old; in fair condition; thirty-six hours ill; diagnosis confirmed by culture; membrane on the tonsils, pharynx, and larynx; one injection of United States Marine Hospital antitoxin; injection produced no effect.

CASES IN WHICH UNFAVORABLE SYMPTOMS WERE, MIGHT HAVE BEEN, AND WERE BELIEVED TO HAVE BEEN, DUE TO ANTITOXIN INJECTIONS.

Only three cases reported to the Committee could by any possibility be placed in this category. All of the details furnished by the reporters are reproduced:

CASE I, by Kortright, Brooklyn: Sudden death in convulsions ten minutes after injection. This case is the already well-known Valentine case, occurring in Brooklyn in the spring of 1895. The principal points were as follows: A girl sixteen years old; in good condition; tonsillar diphtheria; diagnosis confirmed by culture; injected on the first day with 10 cc. Behring's serum; died in convulsions ten minutes later.

CASE II, by Kerley, New York: Fairly healthy boy, two and one-half years old; membrane on tonsils, pharynx, and in nose. Diagnosis confirmed by culture; injected on the morning of the fourth day with 10 cc. (1000 units) New York Health Board serum; temperature at time of injection 100.4° F.; no sepsis, and child apparently not very sick; urine free from albumin. Distinctly worse after injection; in ten hours temperature rose to 103° F.; urine albuminous; throat cleared off rapidly, but marked prostration and great anemia, with irregular fluctuating temperature continued and death from exhaustion with heart failure four days after the use of the serum.

CASE III, by Eynon, New York: Male, three and one-half years old; diagnosis confirmed by culture; two days ill; membrane on tonsils and in nose; two injections New York Health Board serum. "A rapid nephritis developed after the second injection causing coma, convulsions, and death twenty hours after the second injection." In response to an inquiry for further particulars the following was received: "The case seemed a mild one, but the injection was given one afternoon and repeated the following afternoon, about 1500 units in all. The urine up to that time had not been examined. About fourteen or sixteen hours after the second injection unfavorable symptoms began to develop pointing to infection of the kidneys. The urine was found to be loaded with albumin. My impression at the time was that the antitoxin either produced, hastened, or intensified nephritis, thereby causing the fatal termination."

In regard to the three fatal cases just cited, Case I is wholly unexplained. In Case II, the query arises, did this sudden change hinge upon the injection of the serum, or was it one of those unexplained abrupt changes for the worse in a case apparently progressing favorably, so often observed in diphtheria? As regards Case III, it will be seen from the letter that the evidence is not at all conclusive. All details available are given, and the reader may draw his own conclusions.

CLINICAL COMMENTS.

The following are selected from hundreds which have been received, and may be taken fairly to

represent the sentiments of the physicians who have sent in reports:

Dr. Douglas H. Stewart, New York, sends reports of four cases, all desperate ones, and all "presumably fatal under any other form of treatment." Very extensive membrane in all; larynx involved in three; in one neglected case, in a child three years old, *injected upon the fifth day*, the membrane covered the tonsils, nose, pharynx, and larynx. Broncho-pneumonia, nephritis, and sepsis all present. Temperature 107° F. at the time of the first injection. Prostration so great that he dared not attempt intubation. Believes that this case would certainly have been fatal in a few hours without antitoxin. Perfect recovery.

In another case, three years old, membrane first discovered in the left ear; next morning, seen upon the tonsils, and spread in a few hours over the pharynx into the larynx and trachea. Intubation necessary in a few hours; had never seen membrane spread so rapidly as in this child. Urine albuminous; membrane subsequently expelled from larynx and trachea in large casts, with profuse bloody expectoration. Complete recovery on the ninth day. The physician describes this as "the very worst case of diphtheria that has ever come under my notice." Five thousand four hundred antitoxin units were given in four injections. He remarks: "My experiences in the past have been so very unfortunate that the advocates of antiseptics or therapeusis were a constant surarise to me. It has been my fate to have the most desperate cases unloaded upon my shoulders. I had been forced into the belief that the profession was absolutely powerless in the presence of true diphtheria; have lost case after case with tube in the larynx and calomel fumigations at work. Previous to antitoxin, my only hope had become centered in nature and stimulants. In two years have not lost a single case, and surely I may be pardoned if I suffer from diphtheriaphobia in a subacute form, and use antitoxin sometimes unnecessarily."

Dr. L. L. Danforth, New York, states that during his twenty-two years of practice in New York he has seen many fatal cases of diphtheria, had used all kinds of remedies, mainly those of the homeopathic school, and while he had as much confidence in the latter as in anything else, he had seen so many deaths during the year past that he "hailed with delight the advent of antitoxin, and determined to use it." Reports five cases, all of a severe type. "The result in every case has been marvelous. I would not dare to treat a case now without antitoxin."

Dr. H. W. Berg, New York, reporting 14 cases, says: "I have not yet ceased to be surprised at the recovery of some of these cases, which, in the light of my former experience with diphtheria treated without antitoxin, seemed to be irretrievably lost."

Dr. George McNaughton, Brooklyn, reports 72 laryngeal cases, with 24 deaths; 67 of these were intubated, with 21 deaths. He states that he has kept no records of cases other than laryngeal ones, as these seemed the best test of the serum treatment. He believes that if the serum is used early very many cases will not need operation for the relief of stenosis. "I would urge the use of antitoxin in all cases of croup in any patient who has an exudation upon the pharynx; would not wait for bacteriological confirmation of diagnosis, for in so doing valuable time is lost." Has noticed that the tube is coughed up more frequently in injected cases, and believed this due to the fact that the swelling of the tissues subsides at an earlier date.

Dr. D. C. Moriarta, Saratoga, reporting 4 cases, says that the first was a malignant one and "I only used the remedy because I am Health Officer and was urged to do so, as the type of the disease was that from which I have seen recovery but once in eleven years." Boy five years old, four days ill when injected; great prostration, rapid breathing, and he was "practically gone." Nares filled and tonsils and pharynx covered; severe nasal hemorrhage; cervical glands greatly swollen; heart's action very frequent and feeble; child unable to lie down. Behring serum 20 cc. injected; in six hours evidently more comfortable; in eighteen hours decidedly improved; in twenty-four hours sitting up and feeling much better; in forty-eight hours all urgent symptoms gone and membrane loosening. Subsequently had nephritis which lasted six weeks, and multiple neuritis which persisted for three months, but ultimately recovered perfectly. "I send this report because it converted me. No unbiased person familiar with diphtheria could see such results as this and not feel there must be good in it."

Dr. F. M. Crandall, New York, sends report of a child seven years old. Membrane on the tonsils and in larynx, with croup for forty hours when antitoxin was injected and intubation done. Progress of the disease had been rapid; semi-stupor and eyes half open; very feeble rapid pulse; intense toxemia; general cyanosis. Both cyanosis and dyspnea persisted after intubation, showing clearly the presence of membrane below the tube. Case regarded as "absolutely hopeless." The first change was seen in the disappearance of the toxemia, with improvement in the pulse, clearness of the mind, etc.; later a change in the local condition; large masses of membrane were expelled from the larynx and trachea, necessitating frequent removals of the tube. Tube finally removed in a week with complete recovery.

Dr. Reynolds, Baltimore, mentions a case showing the danger of relying too implicitly upon the bacteriological diagnosis. Male, three years. Culture reported only staphylococcus and streptococcus, consequently injection delayed until the fifth day, when membrane covered tonsils, nose, and pharynx. Child died two days later. A sister subsequently contracted the disease, received an-

titoxin on the third day and recovered. The reporter would not wholly rely upon the culture test for diagnosis.

SUMMARY.

1. The report includes returns from 615 physicians. Of this number more than 600 have pronounced themselves as strongly in favor of the serum treatment, the great majority being enthusiastic in its advocacy.

2. The cases included have been drawn from localities widely separated from each other, so that any peculiarity of local conditions to which might be ascribed the favorable reports must be excluded.

3. The report includes the record of every case returned except those in which the evidence of diphtheria was clearly questionable. It will be noted that doubtful cases which recovered have been excluded, while doubtful cases which were fatal have been included.

4. No new cases of sudden death immediately after injection have been returned.

5. The number of cases injected reasonably early in which the serum appeared not to influence the progress of the disease was but 19, these being made up of 9 cases of somewhat doubtful diagnosis; 4 cases of diphtheria complicating measles, and 3 malignant cases in which the progress was so rapid that the cases had passed beyond any reasonable prospect of recovery before the serum was used. In two of these the serum was of uncertain strength and of doubtful value.

6. The number of cases in which the patients appeared to have been made worse by serum were three, and among these there is only one new case in which the result may fairly be attributed to the injection.

7. The general mortality in the 5794 cases reported was 12.3 per cent.; excluding the cases moribund at the time of injection or dying within twenty-four hours, it was 8.8 per cent.

8. The most striking improvement was seen in the cases injected during the first three days. Of 4120 such cases the mortality was 7.3 per cent.; excluding cases moribund at the time of injection or dying within twenty-four hours, it was 4.8 per cent.

9. The mortality of 1448 cases injected on or after the fourth day was 27 per cent.

10. The most convincing argument, and to the minds of the committee an absolutely unanswerable one, in favor of serumtherapy is found in the results obtained in the 1256 laryngeal cases (membranous croup). In one-half of these recovery took place without operation, in a large proportion of which the symptoms of stenosis were severe. Of the 533 cases in which intubation was performed the mortality was 25.9 per cent., or less than half as great as has ever been reported by any other method of treatment.

11. The proportion of cases of broncho-pneumonia—5.9 per cent.—is very small and in striking contrast to results published from hospital sources.

12. As against the two or three instances in which the serum is believed to have acted unfavorably upon the heart might be cited a large number in which there was a distinct improvement in the heart's action after the serum was injected.

13. There is very little, if any, evidence to show that nephritis was caused in any case by the injection of serum. The number of cases of genuine nephritis is remarkably small, the deaths from that source numbering but fifteen.

14. The effect of the serum on the nervous system is less marked than upon any other part of the body; paralytic sequelæ being recorded in 9.7 per cent. of the cases, the reports going to show that the protection afforded by the serum is not great unless injections are made very early.

The Committee feels that this has been such a responsible task that it has thought best to state the principle which has guided it in making up the returns. While it has endeavored to present the favorable results with judicial fairness, it has also tried to give equal or even greater prominence to cases unfavorable to antitoxin.

In conclusion the committee desires in behalf of the Society to express its thanks to members of the profession who have coöperated so actively in this investigation, and to Dr. A. R. Guerard for the preparation of the statistical tables.

SAMUEL S. ADAMS, M. D.,
} Committee.

THE ACTION OF THE SOCIETY UPON THE REPORT.

At the close of its presentation, the Society voted to accept the report of the Committee and after a full discussion it was decided to embody its conclusions in the following resolutions:

1. *Dosage.* For a child over two years old, the dosage of antitoxin should be in all laryngeal cases with stenosis, and in all other severe cases, 1500 to 2000 units for the first injection, to be repeated in from eighteen to twenty-four hours if there is no improvement; a third dose after a sim-

ilar interval if necessary. For severe cases in children under two years, and for mild cases over that age the initial dose should be 1000 units, to be repeated as above if necessary; a second dose is not usually required. The dosage should always be estimated in antitoxin units and not of the amount of serum.

2. *Quality of Antitoxin.* The most concentrated strength of an absolutely reliable preparation.

3. *Time of administration.* Antitoxin should be administered as early as possible on a clinical diagnosis, not waiting for a bacteriological culture. However late the first observation is made, an injection should be given unless the progress of the case is favorable and satisfactory.

The Committee was appointed to continue its work for another year and was requested to issue another circular asking for the further coöperation of the profession, this circular to be sent out as soon as possible in order that physicians may record their cases as they occur through the coming year.

CLINICAL MEMORANDUM.

A CASE OF EPILEPSY AND MIGRAINE, APPARENTLY DEPENDING UPON EYE-STRAIN.[1]

BY F. W. MARLOW, M.D.,
OF SYRACUSE, N. Y.
PROFESSOR OF OPHTHALMOLOGY IN THE MEDICAL DEPARTMENT OF SYRACUSE UNIVERSITY.

ALTHOUGH it has been asserted by some writers that epilepsy and migraine do not occur in the same individual, a number of cases has been recorded which prove the reverse to be true in exceptional cases. Liveing[2] records in detail some interesting cases of this kind. In these, for the most part, the attacks commenced and continued for years as attacks of sick headache, afterward becoming epileptic in character; or attacks of epilepsy alternated with attacks of sick headache.

Gowers,[3] also, states that he has seen twelve cases in which both affections occurred in the same individual. In seven migraine had existed for several years, and the patients afterward became epileptic. In five of these seven the migraine ceased, or diminished greatly, when the epilepsy developed. In the five remaining cases the attacks were sometimes epileptic and sometimes migrainous in character. I have myself in three cases noted the occurrence of both maladies in the same patient.

One of Liveing's cases is sufficiently suggestive of the present one to justify the repetition of it here briefly. A girl, eighteen years old, complained of a peculiar kind of headache, from which she had suffered eighteen months; previously feels unwell and depressed, then has a sense of oppression in region of heart, then becomes momentarily confused and speechless. It does not appear that consciousness is lost, as she remembers what is said at the time. Sometimes there are no premonitory symptoms. These symptoms are now invariably followed by a severe frontal headache, terminating in a heavy sleep of three or four hours' duration. Sometimes two attacks occur in a day. Once the headache was absent, but the sleep occurred as usual.

Olmerod says that a patient described to him attacks commencing with symptoms of sick headache and ending with an epileptic seizure.

The patient, an unmarried woman, aged thirty years, was first seen by me on October 10, 1890. She had been subject to what she called a common sick headache from early childhood, occurring perhaps once or twice a year, but at about fourteen years of age became subject to a much severer type of headache, occurring twice or three times a week during the whole period of time she was subject to it, with the exception of one interval of seven weeks. The ordinary duration was from twenty-four to thirty-six hours, but some attacks lasted three days. As a rule, there was no warning or premonitory symptoms, but occasionally for an hour or two before pain commenced there was a "strange, tight feeling," in the top of the head, and so much dizziness that she couldn't walk. The pain was situated between the eyes and in the back of the head, was most intense in character, and was accompanied from the start or within two hours of it, by constant nausea and uncontrollable vomiting. Latterly she had in some attacks, in her own words, a "sort of spasm in which I would set my eyes and straighten back, and know nothing for perhaps five minutes." For the pain and vomiting ether and chloroform were commonly administered, and sometimes morphin subcutaneously.

There was no difficulty in finding the right words, or in thinking; but the feeling of sickness was so great that it was an effort to speak. Her tongue and arms got very numb during the attack and sometimes her legs also. No loss of memory followed the attacks; on the contrary she never felt brighter than immediately after one. The attacks commenced either during the day or night, with a tendency latterly to begin in the daytime. There was no drowsiness during the attack, and even the subcutaneous injection of morphin failed to produce sleep. After the headache was over she commonly slept for a short time.

Her father used to have very severe headaches until he partially lost the sight of one eye twelve years ago, since which time the severe headaches have not occurred. An aunt, also, was subject to sick headaches and died suddenly in a nervous seizure of some kind.

It will hardly be denied that the diagnosis of an unusually severe type of sick headache was completely warranted by the symptoms, which may be briefly summarized as follows: Periodic headaches accompanied by nausea and vomiting, and with numbness of tongue and extremities, commencing in early childhood, and occurring in a patient with a family history of sick headaches. That, at any rate, was my diagnosis at the time, and remained so until recently, when the description of an attack by an eye-witness caused me to modify it.

[1] Reported before the Syracuse Academy of Medicine.
[2] "Treatise on Megrim and Sick Headache."
[3] "Diseases of the Nervous System."

In one attack seen, the patient dropped suddenly and without warning from the chair in which she was sitting, in a completely unconscious state, became rigid, arms and legs stiffening out, frothed at the mouth, and there were some slight convulsive movements. The unconsciousness lasted two hours, and was immediately followed by severe nausea and intense headache.

On another occasion the attack came on while on the cars, and just as she was about to pass out through the doorway. In falling she grasped the handle of the door, which she held in so rigid a spasm that it was only disengaged with great force. It required three men to get her out of the train, and she was ill with headache and vomiting for three days afterward.

It became evident therefore, that whatever name might be given to the termination of the attack, the onset consisted of a typical epileptic seizure.

It is scarcely necessary to state that every physician, regular and otherwise, in the neighborhood of her home had been consulted, but without benefit. From the age fifteen to eighteen years there was a complete suppression of menstruation, to which the attacks were at that time attributed. A five month's residence and treatment in the private hospital of a New York gynecologist resulted in a restoration of this function, but made no difference whatever to the frequency or severity of the so-called headaches. She was treated also in other cities, but without benefit. It was, therefore, with but little expectation of relief that she acted upon the suggestion of a friend, and had her eyes examined.

She has always been in the habit when reading of looking sideways, turning the eyes to the left, and also suffered from some twitching of the right eyelid and side of nose, and has a tendency to hold objects very near, although her distant vision is good.

Examination shows

R. V. $\frac{6}{6}$; + 0.25 D. cyl. ax. 60° improves.
L. V. $\frac{6}{12}$; + 0.75 D. cyl. ax. 100° improves.

Tests for muscular equilibrium shows practical orthophoria.

After homatropia:

R.V. $\frac{6}{12}$; + 1.25 D. S. ⊃ + 0.25 D. cyl. ax. 60° = $\frac{6}{6}$–
L.V. $\frac{6}{12}$; + 0.50 D. S. ⊃ + 0.75 D. cyl. ax. 100° = $\frac{6}{6}$–

Prescribed for constant wear:

R. + 1. D. S. ⊃ + 0.25 D. cyl. ax. 60°.
L. + 0.25 D. S. ⊃ + 0.75 D. cyl. ax. 100°.

Five years and a half have now elapsed and she has had no recurrence of the attacks, and has had no other treatment. Within six months of the time she commenced to wear glasses she had gained twenty pounds in weight.

This case brings up the question of the difference between *idiopathic* and so-called *reflex* epilepsy. We know epilepsy only by its history and symptoms; of its pathology nothing is known. All statements regarding it are hypothetical or conjectural. It is generally admitted by writers on the subject that the symptoms of the idiopathic are indistinguishable from those of the so-called reflex form. It is also admitted that convulsions due in the first place to the irritation of intestinal worms, may continue after the worms are discharged as idiopathic epilepsy. Furthermore, the peripheral source of the so-called reflex attack may be extremely difficult to discover. This being doubtlessly true, it will not be denied that the peripheral source is sometimes not found at all, though it exists, and that the failure to discover it in any case is not a proof of its non-existence. We also find the assertion under the heading of prognosis that reflex epilepsy may be cured by the removal of its peripheral source of irritation, whereas the cure of a case of idiopathic epilepsy is most exceedingly rare. All of which amounts to this, that so long as epileptic attacks remain unchecked by the removal of the peripheral irritation or strain upon which they depend they are to be considered idiopathic in character, but as soon as the removal of this strain prevents the recurrence of the attacks, they are to be classed in the far less serious and important category of reflex convulsions. It is easy to understand on this very simple method of classification, why idiopathic epilepsy is so very rarely amenable to treatment. It doubtless resembles other functional disturbances, in not ceasing until its cause is removed.

The present case bears strongly on this point. It presents many—all the necessary characteristics of the idiopathic disease. Occurring in a patient with a family history of sick headache, possibly of epilepsy, commencing early in life, replacing attacks of ordinary cephalalgia the attacks being absolutely sudden in their onset, with total unconsciousness and convulsions, terminating in an attack of typical sick headache, commencing sometimes in the night and sometimes in the day, and occurring at short intervals for a period of sixteen years, during which time she was treated by many physicians in her own neighborhood and elsewhere without any relief, it is hardly likely that any of these physicians would have hesitated to declare it a case of true idiopathic epilepsy.

From the standpoint of history, symptoms, and associations, this was a case of idiopathic epilepsy; from the standpoint of its cure, a case of reflex epilepsy.

It emphasizes the importance of removing all sources of peripheral irritation or strain, even when all indications are in favor of the case being idiopathic in nature.

MEDICAL PROGRESS.

The State of the Blood Attending Metastatic Carcinosis of the Bone-Marrow.—Epstein (*Zeitschrift für klinische Medicin*, B. 30, H. 1, 2, p. 121) has reported the case of a woman, without hereditary predisposition, who complained of pain in the right lower extremity, and especially referred to the femur. The patient was languid and emaciated, although the appetite was preserved. From time to time there was vomiting, and there was increased thirst. Following a tepid bath hematemesis occurred, and the stools contained coffee-ground like material. Subsequently nose-bleed occurred frequently. The skin and mucous membranes were waxy-yellow in appearance. The pulse and respiration were accelerated, although temperature was slightly below normal. The

lymphatic glands at the left angle of the lower jaw and at the flexures of the elbows and groins were enlarged, hard, and movable. Each breast contained a firm nodule, and the nipple was retracted. The percussion-note at the apices of the lungs, and over the remaining anterior portion, was hyper-resonant upon the right, but upon the left the resonance was impaired. Upon the right the breathing was vesicular and upon the left harsh. At the apex of the heart a systolic murmur was audible, increasing in intensity in the direction of the pulmonary artery. The stomach was displaced downward. The area of hepatic percussion dulness was slightly increased. The lower extremity of the spleen was palpable. The urine was passed in diminished quantities, but presented no other abnormality. The uterus was dragged to the right and backward and was retroverted. The right lower extremity was painful and flexed at the knee-joint. In the progress of the case the pulmonary percussion dulness was increased over the whole left chest, and fine moist râles were heard. Over the heart systolic and diastolic friction murmurs became audible. A purulent discharge took place from the left ear. The patient grew gradually weaker and finally died in collapse. Upon *post-mortem* examination cirrhosis carcinoma of the left breast was found, with metastases in the right breast, in the axillary, cervical and mediastinal glands, in both tonsils, in the lymphatics of the pleura, in the gastric mucosa, in the dura mater, and in the left mastoid process; as well as in the bone-marrow of all the bones examined. The blood contained only nineteen per cent. of hemoglobin. Exact estimations of the number of corpuscles could not be made, but a study of cover-glass preparations disclosed a high degree of oligocythemia. The red blood-corpuscles were very variable in size and many were nucleated; some of the nuclei had evidently undergone fragmentation. The red cells, and especially the nucleated ones, were distinctly polychromatophilous. The proportion of red to colorless corpuscles varied from one to twenty-five, and one to forty. The increase in the number of the colorless cells involved especially the large mono-nucleas form, the majority of which presented netrophule granulations. Cells resembling myelocytes were also found. But two eosinophil cells were found.

Active and Passive Immunity to Cholera, Typhoid Fever, and Allied Disease-Processes.—PFEIFFER (*Deutsche medicinische Wochenschrift*, 1896, No. 15, p. 232), formulates in the following propositions the results of his investigations upon the subject of immunity: The cholera poison is contained in the body-substance of the cholera-vibrio, so that dead, as well as living cholera bacilli show marked toxic properties. The cholera poison becomes capable of absorption by the disintegration of the cholera bacteria; analogous conditions have been established as regards typhoid fever, anthrax, chicken cholera, staphylococcus infection, and apparently influenza. Animals may be rendered immune to toxic doses of living cholera spirilla, and typhoid bacilli by previous treatment with various substances of bacterial and non-bacterial origin. This protection is transient, and does not depend upon specific changes in the fluids of the body, and is designated as resistance, in contradistinction to specific immunity. In the blood-serum of human beings and animals that have been exposed to the action of living or dead cholera spirilla or typhoid bacilli, there occur specific protective bodies, which are thus capable of rendering aid in differential diagnosis in cases in which ordinary methods have failed; and these substances may be made to accumulate in the blood in concentrated degree by properly conducted immunization. In their relation to chemic and physical agencies, they bear a close analogy with the antitoxins, from which, however, they are differentiated by their action. While the antitoxins occupy a specific relation to certain poisons, and are capable of destroying these in the animal body, the anti-bodies of cholera and typhoid fever are incapable of thus acting upon the poison of typhoid bacilli and cholera spirilla. Their activity consists in the destruction of the bacteria, but this property makes itself manifest, as a rule, only in the body, and is capable of demonstration outside the body only under special circumstances. These anti-bodies are also found, though in small quantities, in the normal blood of animals and human beings. They are neither bacterial products deprived of virulence, nor combinations of these with components of the immunized organism, but they are probably entirely new substances resulting from the specific reaction of the body to a specific irritant. The evidence points to the view that the anti-bodies are specific ferments. It is possible that the antitoxins also are specific enzymes. As fermentative activity plays an important part in the production of natural immunity, it is possible to relate natural and acquired immunity, antitoxic and bactericidal functions to a common general principle.

Post-diphtheritic Paralysis a Month after Serum Treatment.—FILLIATRE (*Gazette Hebdomadaire de Médicine de Chirurgie*, 1896, No. 33, p. 385) has reported the case of a child, nearly three years old, presenting symptoms of croup, which proved on bacteriologic examination to be diphtheritic. An injection of fifteen c.cm. of antitoxic serum was at once made into the right flank, and forty-eight hours later a second injection of ten c.cm. into the left flank. In the course of twelve hours, the false membrane had completely disappeared, the child breathed easier, the pulse was normal, the fever had disappeared, and only the sub-maxillary adenopathy remained. The child continued well for more than a month, when it was observed to speak through the nose. A day later, speech was almost unintelligible, and saliva dribbled from the mouth. In the course of several days more, the head could not be held up, the chin falling upon the chest. Deglutition also became difficult. The knee-jerks as well as the pupillary reflexes, were preserved. Sensibility was intact. The muscles, especially enfeebled, were the extensors of the neck, the rotators of the head, excepting the sterno-mastoid, the supra-spinous, and the elevators and abductors of the scapulæ. The fascial muscles also were largely affected, as well as the recti abdominis. Under electric treatment, improvement rapidly set in, and soon proceeded to final recovery.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

ANTITOXIN IN DIPHTHERIA; THE COLLECTIVE INVESTIGATION.

THE AMERICAN PEDIATRIC SOCIETY'S REPORT, the full text of which appears in this issue of the NEWS, is worthy of the careful perusal of every physician interested in the subject of diphtheria. It is the first time that an investigation has been attempted on such an extensive scale of cases drawn exclusively from private practice, and forms a fitting conclusion to the antitoxin discussion which has been going on in our journal for the past few weeks.

Statistical evidence may be worth much or little according to the purpose with which it has been gathered. Its value depends mainly upon four factors: the number of cases; the conditions under which they have been observed; the accuracy with which they have been reported; and the care and honesty with which they have been analyzed. Let us look at the Society's Report with these points in mind.

While a report of fifty or a hundred cases is of value and may be convincing to the mind of the physician who has observed them, they are not conclusive. To establish any point in a disease like diphtheria, the figures must be large enough to include groups, not only of mild but of severe cases, or, in other words, large enough to represent all the variations of the disease. The number of cases in the report—nearly six thousand—is great enough to warrant some positive deductions. That the Committee were able to secure so large a number of cases is indeed surprising, and cannot fail to show how strong a position antitoxin already has in the judgment of the physicians of this country.

In an acute disease, cases observed under special conditions are not to be depended upon to determine the value of any mode of treatment, *e.g.*, statistics taken exclusively from hospital practice, those of cases of a certain age, or from a single locality, or from one epidemic, do not represent the facts of a disease so well as when they are drawn from widely-scattered districts and are observed under varying conditions. Reports from 114 cities and towns are much more valuable for evidence than if all the cases had been treated in New York or Philadelphia, where the special characteristics of the local epidemic would need to be taken into account. In the recent discussions of diphtheria in New York, the results obtained in the Willard Parker Hospital have figured altogether too prominently. The number of cases treated there is not large, and the conditions are somewhat peculiar. Moreover, the present results are useful only for comparison with previous years, and are in no sense to be compared in importance with the results obtained with antitoxin in the wide field of general practice. The Committee has endeavored to reach as large a number as possible of physicians who have used antitoxin, and has succeeded in obtaining reports from over six hundred. Of this number, almost all have recorded themselves as strongly in favor of the antitoxin treatment. A general conclusion reached by so many physicians carries great weight—much more weight than would the same number of cases treated by a score of physicians. The report may thus be taken as a vote upon the value of antitoxin by over six hundred American physicians.

As an example of a faulty mode of collecting cases, let the reader study the paper of Dr.

Stowell in the MEDICAL NEWS of June 20th or the New York *Medical Record* of same date, where the purpose of the writer has apparently been to collect from medical literature all the reports possible in which there was a low mortality. Such a collection of cases proves nothing even though they aggregate thousands except, perhaps, that diphtheria is sometimes mild, as we all know. Such tables represent a very favorable, but a very fallacious, showing, and are entirely without value in determining what the mortality of diphtheria really is.

Any set of figures may be twisted, as everyone knows, to prove propositions which are diametrically opposed to each other, according to the bias of the person who analyzes them. The work of the Committee in this respect is a model of fairness and justice. That the facts reported have been presented without prejudice is, we think, evident upon every page. The position taken by the Committee in excluding mild cases not confirmed by bacteriological examination is a very proper one, although by this fact the percentage of mortality has certainly been raised; while, by including doubtful cases which terminated unfavorably, the report obviates the criticism of having excluded any evidence unfavorable to antitoxin.

The general result of the analysis of these cases is decidedly favorable to the antitoxin treatment, and the report as a whole is, we think, the strongest evidence which has yet been brought forward. Let us look at a few points in detail: First, the results obtained in cases under two years. It is well known that the mortality of such cases is always high, whether observed in private or public practice. That 867 cases were treated, with a mortality of only 23.3 per cent., is a remarkable showing; or, excluding moribund cases, 19.2 per cent. Again, a mortality of 25.9 per cent. in 533 cases of laryngeal diphtheria requiring intubation, is a record which has never been approached. Whatever may be said of the results obtained in pharyngeal diphtheria, and low mortality figures have been published by many other methods of treatment, we think the committee is right in stating that it is by the results in the laryngeal cases that the real value of antitoxin is to be tested. Upon this point the evidence of the report in favor of antitoxin seems to be conclusive.

So much has been said in hospital reports concerning the frequency of broncho-pneumonia following antitoxin, that we look with special interest to see what the report has to say concerning this complication. The percentage of broncho-pneumonia (5.9) is remarkably small, and it is still more remarkable that broncho-pneumonia was ascribed as the cause of death in only about one-seventh of the fatal cases. This is in strong contrast with hospital results, and points to the fact that it is "hospitalism," and not antitoxin, which is responsible for the prevalence of the pneumonia.

It is to be regretted that the reports sent in to the Committee did not furnish fuller details regarding nephritis. Examinations of the urine are so frequently neglected in private practice that the data on this subject were quite imperfect. Whatever the frequency of nephritis may have been in the cases, there were only fifteen in which this was assigned as the cause of death—a very small proportion, as compared with general results.

The profession certainly owes the Society and the Committee a debt of gratitude for having collected such a mass of data relating to the treatment of diphtheria. It has been patiently awaiting a fair statement of all the facts, not one side of the question, and in this report we think all the facts have been fairly presented. We are glad to note that the work of the Committee is to be continued for another year.

THE PRESENCE OF THE LEPRA-BACILLI IN THE MEDULLA OF A FATAL CASE OF SYRINGOMYELIA.

IT has been contended by some observers that the symptoms included in the designation syringomyelia is really but a manifestation of leprosy, and it must be admitted that there is, at times, a considerable resemblance between the two sets of phenomena. There is, however, abundant clinical evidence that the two morbid processes are distinct, although in one case of syringomyelia lepra-bacilli were found in some of the peripheral nerves. PESTANA and BETTENCOURT (*Centralblatt für Bakteriologie, Parasitenk. u. Infektionskrankh.*, B. XIX, Nos. 18, 19, p. 698) now re-

ports a case of syringomyelia in which, with characteristic phenomena, lepra-bacilli were found at the site of the lesion in the medulla oblongata. The patient was a man forty-six years old, without hereditary predisposition, in whom symptoms of syringomyelia had been present for three years. At first there had been weakness of the left arm, with increasing intensity, followed a year later by similar weakness in the right arm. In the meantime it was noticed that contact with hot bodies was unattended with discomfort. Examination showed that the upper extremities were insensitive to heat and cold, and in less degree to touch. Later weakness appeared also in the lower extremities, and the muscles first affected began to undergo atrophy. Tactile and thermic insensibility increased in degree and extent, involving, however, principally the right side, and painful sensibility also became diminished and in places lost. The wasting and the weakness, with fibrillary contractions, were, on the other hand, the more marked upon the left side. The case thus progressed to a fatal termination. Upon *post-mortem* examination the cord was found enlarged in the cervical region in consequence of the presence of a dark-gray mass—which proved to be gliomatous—and in the midst of which excavation had taken place. The disease extended from the cervical enlargement to the medulla and had given rise to inflammatory and degenerative changes in adjacent portions of the cord. Bacterioscopic examination of sections of the affected medulla disclosed the presence of numerous lepra-bacilli.

OPHTHALMOLOGY.

A CRITICAL RESUME OF RECENT PROGRESS.

Experiments with the Röntgen rays have been conducted in relation to nearly all of the special branches of medicine, including ophthalmology. While no brilliant beneficial results have been arrived at, and it is not expected that the Röntgen rays will confer much benefit on suffering humanity when applied to ophthalmology, the experiments have developed certain facts which are of interest to those who are working in this particular branch of medicine.

Dr. Van Duyse (*Arch. d'Ophthalmologie*, February, 1896) experimented with rabbits' eyes, introducing pieces of lead into the anterior segment of the globe, and obtained skiagraphs by placing a sensitized plate below the head and projecting the X-rays from the Crookes' tube from above, giving an exposure of twelve minutes. The location of the foreign body could be readily determined by this means. Van Duyse is of the opinion that this procedure may be of value when the piece of metal is lodged in the anterior segment of the human eye. He suggests, however, that the cryptoscope of E. Salviani or fluoroscope of Edison may be utilized for the purpose of locating a foreign body, making it unnecessary to obtain a shadowgraph. Exposures of the human eye are made by Van Duyse by placing the plate as far back at the inner canthus as possible, projecting the X-rays from the temporal side. In order to produce marked prophthalmus he suggests injecting sterile, normal saline solution into Tenon's capsule, causing the solution to pass behind the globe and to push the globe forward.

Dr. F. C. Harousch (*Annal. of Ophthal. and Otol.*, vol. v, p. 267) has made a number of experiments with the X-rays on pigs', calves', and lambs' eyes, with and without the introduction of metallic foreign bodies. The time of exposure was forty-five to fifty minutes. Where satisfactory exposures could be obtained, the position of metal foreign bodies in the eyes could be readily determined. An interesting point observed was the relative resistance of the various parts of the eye to the Röntgen rays. The obstruction offered to the rays increased in the following order: (1) Capsule of lens. (2) Choroid and retina. (3) Sclerotic. (4) Cornea. (5) Vitreous body. (6) Lens. Knowing that the X-rays produce no sensation of vision when they reach the retina through the cornea, lens, and vitreous, experiments were made to determine the effect of the X-rays on the retina when passed through the sclera and choroid. No sensation of light was produced. An attempt was made to locate a piece of steel in the interior of an eye, which had entered the eye eight weeks before the patient came under observation. Iridocyclitis was present. A ciliary staphyloma, 2 mm. in diameter, was observed situated 6 mm. above the margin of the cornea; vitreous hazy; no

foreign body could be seen. A skiagraph of the anterior segment of the globe was obtained by placing the sensitive photographic plate on the temporal side, and projecting the X-rays over the bridge of the nose. A dark line was seen in the negative which was thought to represent the shadow from the foreign body, situated near the base of the staphyloma, but on making an incision into the globe at the point indicated no foreign body was found.

The experiments briefly referred to above have developed the fact which is of scientific interest, that the transparent media of the eye offer obstruction to the passage of the X-rays similar to that of glass. The fact is also demonstrated that the Röntgen rays have a very limited application in ophthalmology.

The treatment of diphtheritic affections of the eye, by the use of the Roux-Behring antitoxin, has excited no little interest in France, England, and Germany, very gratifying results having been reported. Diphtheria of the conjunctiva is of relatively rare occurrence in the United States; however, it does occur, and is so rapidly destructive to vision that it is important to know that we possess a remedy potent in arresting its ravages. Coppez has contributed two articles on the subject (*Jour. de Med. et de Chir. de Brux.*, November 24, 1894, and *Rev. Gen. d'Ophthal.*, 1896, p. 51). The first case reported occurred in a child of nineteen months. Loeffler's bacillus was demonstrated by culture methods. At the time the injection was made the conjunctivæ of the lids of both eyes were covered with pseudo-membrane, and the corneæ were hazy. An injection of 10 c.cm., 1600 units Behring, was given. In forty-eight hours the membrane had disappeared. The child made a good recovery. In a second case, occurring in a child of sixteen months, the false membrane was present on the conjunctiva of one eye only. The Loeffler bacilli were present. Ulcer of the cornea developed on the day after the injection was made. The membrane was gone on the fourth day. The corneal ulcer healed, having done but little damage to the cornea. No membrane developed on the conjunctiva of the fellow eye. Coppez attributes the non-appearance of pseudo-membrane on the conjunctiva of one eye to the prophylactic effect of the antitoxin. Hamilton and Emery (*Br. Med. Jour.*, 1895, p. 1419) report a case of diphtheria of the conjunctiva following scarlatina and accompanied by faucial diphtheria. Both eyes were affected; ulcer of the cornea of one eye. Two injections, each of 10 c.cm. of antitoxin, were given in the first twenty-four hours. Improvement began almost immediately. Four days later a third injection was given as pseudo-membrane had again appeared in the throat. There was perforation of the right cornea, but recovery with good vision occurred. Schmidt-Rimpler (*Centralbl. f. p. Augenheilk.*, 1895, p. 353) reports the treatment of three cases of post-diphtheritic paralysis of the accommodation, treated by injections of antitoxin, and states that in his opinion recovery took place much more rapidly than would have been the case if the antitoxin had not been employed. Favorable reports of the effect of serumtherapy in diphtheria of the eye have also been made by Morax, Konigshofer, Recken, Darier, and others. The results obtained were good in all cases reported.

Of the remedies that have recently attracted attention in ophthalmological therapeutics, formic aldehyde is probably the most important. The preparation used is that known as formalin. It is a forty per cent. solution of formic aldehyde. The solutions mentioned below are dilutions of formalin. Guaita (*Ann. d'Ottal.*, v. xxiii, p. 360) was one of the first to exploit the excellencies of this remedy in ophthalmic practice. The immediate germicidal power of formic aldehyde is much inferior to solutions of the sublimate of similar strength, but its great diffusibility, due to the absence of any tendency to coagulate albumin, renders it of greater value as an antiseptic. Cutting instruments are not affected by it. Guaita found formalin of value in the treatment of corneal ulcers, infected wounds, purulent and mucopurulent conjunctivitis, and trachoma. He employed a solution of 1–100 to touch the corneal ulcer, and gave a solution of 1–2000 to be used as a collyrium every four hours. Formalin in solution of 1–1000 or less is somewhat irritating to the conjunctiva, but in solution of 1–2000 it produces no unpleasant sensation; in this strength the remedy is harmless. Valude (*Recueil d'Ophthal.*, 1893, p. 431) substantiates the claims regarding the value of formic aldehyde as

set forth by Guaita, he has found it efficacious in post-operative infection, instilling a solution of 1–1000 into the eye every three hours. Davidson (*Br. Med. Jour.*, 1896, p. 144) uses a solution of formalin (Schering) 1–2000 to 1–3000, directing that it shall be dropped into the eye freely every hour—a virtual lavage of the eye. Employed in this way it has proven to be of great value in cases of infected corneal ulcer, with or without hypopion. One of the cases reported by Davidson is briefly as follows: Prolapse of the iris accompanying a perforating lacerated wound of the cornea, in its lower half, incurred four days previously. Status praesens: Infiltration of corneal tissue adjacent to the wound; hypopion; iritis. Treatment: atropin, one per cent. instilled two or three times daily. Eight or ten drops of a 1–2000 solution of formalin was dropped into the eye every hour when the patient was awake. When seen the next day the cornea was clear, hypopion gone, iris fairly well dilated, no pain. Burnett (*Ophthalmic Record*, 1896, p. 310) has met with much success in the use of formic aldehyde in the treatment of corneal ulcers, muco-purulent and purulent conjunctivitis. He employes the Schering preparation in the strength of 1–1000 to and 1–2000, applied every four hours.

John E. Weeks, M.D.

ECHOES AND NEWS.

The Pasteur Chair.—Until recently there has been no appointment to fill the Chair in the French Academy of Medicine left vacant by the death of Pasteur. It will now be occupied by Dr. Roux who has been made an associate.

Changes in the Medical Department of the University of Pennsylvania.—At a meeting of the trustees of this institution on June 23d, Dr. Alexander C. Abbott was chosen Professor of Hygiene to succeed Professor John S. Billings, resigned.

Rush Medical College.—Professor Edwin Klebs has been elected to the Chair of Pathology in Rush Medical College. This college has recently been recognized by the Examining Board of the Royal College of Physicians and the Royal College of Surgeons, London, England. This recognition entitles its alumni to all the privileges accorded to the graduates of other institutions recognized by that Board.

Electricity as a Hemostatic.—Mr. Lawson Tait has invented an instrument by means of which the electric current can be very successfully applied to control bleeding. We have not yet seen a full description of his method.

Typhoid Fever at Plymouth Again.—In 1885 a most serious epidemic of typhoid fever raged at the little town of Plymouth, Pa. The water supply has again become polluted, and for the two weeks past there has been an alarming increase in the spread of this disease with a number of deaths. Efforts to purify the water have not met with success, and much fear is entertained by the local profession for the safety of the populace.

Vaccination of Sheep.—A member of the Pasteur Institute of Algiers has discovered a vaccine that will prevent "sheep-rot." All animals vaccinated either escape or have a mild form of the disease, from which they invariably recover.

Death of Dr. Choate.—We record with deep regret the sudden death of Dr. George C. S. Choate, which occurred in New York on June 28th. Dr. Choate was a brother of Mr. Joseph H. Choate, the famous member of the New York bar. Nearly a half century of his life has been spent in the practice of medicine in New York and Massachusetts, his native State. Besides a large practice in New York City, he has for many years maintained a private asylum at Pleasantville, Westchester Co., and it was there that Horace Greeley died in 1872. Dr. Choate continued in active practice until his death.

A Skiagraph of Li.—While in Germany recently the Chinese statesman, Li Hung Chang, took advantage of an opportunity to have the bullet which he carries in his cheek located by the Röntgen rays. It will be remembered that when in Japan, arranging the treaty of peace between that nation and his own, he was assaulted by a would-be assassin, who, it was feared at the time, had been only too successful in taking the life of this truly great man. The picture secured shows the tract of the wound through the tissues of the cheek and the encysted missile slightly below the point of entrance.

The Cavendish Lecture.—On the evening of June 17th, Mr. Thomas Bryant, ex-President of the Royal College of Surgeons of England, delivered the Cavendish Lecture to a large audience at the West End Hospital, London. The subject of the address was "Jenner and his work."

Creolin.—This popular antiseptic agent has been generally accorded entire freedom from toxic effects, but, in the light of some recent experiments upon lower animals, this superiority must be called in question. Professor Hobday of the Royal Veterinary College, England, reports in the *Lancet* that two ferrets subjected to applications of the drug, diluted with water in the proportion of two ounces to a quart, died in half an hour. Subsequent investigation proved it to be an irritant and narcotic poison to both dogs and cats, especially when applied over a considerable area of the body. Such a report emphatically suggests caution in treating extensive wounds upon the human body with creolin as a dressing.

Medical Longevity.—Rare opportunities, together with a predilection for such investigation, has allowed Dr. Salz-

mann of Esslingen, to present us with some reliable and quite interesting figures relative to the average length of life among medical men. During the sixteenth century he found it to be only thirty-six years and seven months —in the seventeenth century, forty-five years and eight months; in the eighteenth century it reached forty-nine years and eight months, while in the present century fifty-six years and seven months. The addition of twenty years to the average life of the physician has been the result of advancing scientific knowledge both as relates to prevention and cure.

A New Hypnotic.—From a species of cactus, known to the Mexicans as "Pellote," Dr. Hefter of Leipzig, has separated the active principle which he has named Pellotin. Professor Jolly of Berlin, has made a number of experiments with it upon patients in Charité Hospital, Berlin, following those previously made by Dr. Hefter upon animals and himself. He found that three quarters of a grain would almost always cause several hours of sleep, and that no subjective symptoms followed its use beyond a little giddiness in about twenty per cent. of the patients. He observed, however, a marked influence upon the pulse rate which was ten to twenty beats lower during sleep, but returned to normal on waking. It is estimated that half a grain is equivalent to fifteen grains of trional or thirty grains of chloral hydrate. The alkaloid is quite insoluble, hence the hydrochlorate is always employed.

Alcohol and Sunstroke.—During the month of January there occurred over three hundred deaths from sunstroke in Australia. When called upon to offer suggestions relative to its prevention the Medical Board promptly informed the Colonial Government that of all the predisposing causes none was so potent as undue indulgence in intoxicating liquors—and in its treatment nothing seemed to have a more disastrous effect than the administration of alcoholic stimulants. After this precaution, suggestions were offered regarding the selection of proper clothing, etc.

The Death of Dr. Langerhaus' Son Explained.—A full and satisfactory explanation of the sudden and tragic death of the little son of Dr. Langerhaus immediately following an injection of antitoxin serum has been reached through the subsequent investigation. In the first place the analysis of the serum proved it to be reliable, and no irregularity in the method of its administration could be discovered. It was found however that the child had just completed an unusually heavy meal, and as the necropsy showed his larynx and treachea well filled with a material identical with that found in his stomach the accepted inference is that while faint from the shock of the injection he was unable to eject the vomited matter from his throat and instead drew it into the air passages with fatal effect. It may be concluded then that what appeared to be quite damaging evidence against the serum is really the result of a very simple accident.

The Philadelphia Water Supply.—The Municipal Council of Philadelphia is very properly devoting much attention to the betterment of the water provided for their city. The modern method of filtration is generally favored, and a large corporation has presented a proposition promising to procure daily 350,000,000 gallons of water from the Delaware River above the city and subject it to this process. No more important economic question can engross the thoughts of a community than the condition of its water supply.

The Medical Society of New Jersey.—The New Jersey State Medical Society closed a successful meeting at Asbury Park on June 24th. The subject of the antitoxin treatment of diphtheria occupied the attention of the body. A prolonged and spirited discussion showed the members divided in their estimate of its value. The new officers elected were: President, F. J. Smith of Bridgeton; first vice-president, D. C. English of New Brunswick; second vice-president, C. R. P. Fisher of Bound Brook; third vice-president, Luther M. Halsey of Newark; corresponding secretary, E. L. B. Godfrey of Camden; recording secretary, William Pierson of Orange; treasurer, Archibald Mercer of Newark. The next annual meeting will be held at Atlantic City in June, 1897.

Living Greek in the Schools of France.—Dr. A. Rose's public lecture on the proper pronunciation of Greek, which he gave on June 5th, in the New York Academy of Medicine, was a social and philological success. It will be remembered that the meeting was presided over by Dr. S. Stanhope Orvis, Professor of Greek of the University of Princeton. And addresses were delivered by Hon. D. N. Botassi, Consul-general of Greece, Mr. Charles E. Sprague, the president of the Union Dime Savings Bank and a Philhellen besides, and by Professor Leotsakes. Now it appears that it is to become an event of unusual significance. Almost simultaneously with this meeting the Greek journals brought the official news that the French Government had ordered the abandonment of the Erasmian, and the introduction of the living Greek, pronunciation in all the schools of the French Republic in which Greek is taught, and had induced the Greek Government to call together a committee, under the presidency of the Minister of Public Instruction in Greece, for the purpose of making propaganda for the introduction of the living Greek pronunciation in other countries besides France. The first steps toward the appointment of such a committee has been taken by the Greek ambassador in Berlin. The committee will publish a scientific work to prove the correctness of the living Greek pronunciation; to show the advantages of the introduction of living Greek in place of Erasmian pronunciation, and finally to prepare a memorandum instructing the representatives of Greece in foreign lands how to act in the matter. The facility with which living Greek is acquired by the natural method of speech places it on a par with any other modern language. Indeed, with the introduction of living Greek in all the schools of the civilized world, the idea of having Greek for an international language for medical schools does not appear so Utopian as some have pronounced it.

SOCIETY PROCEEDINGS.

SECOND ANNUAL MEETING OF THE AMERICAN LARYNGOLOGAL, RHINOLOGICAL, AND OTOLGICAL SOCIETY,

Held in New York City, April 17 and 18, 1896.

EDWARD B. DENCH, M.D., of New York, President.

FIRST DAY—APRIL 17TH.

THE DIAGNOSTIC VALUE OF OPHTHALMOSCOPIC EXAMINATION IN CEREBRAL DISEASE DEPENDING UPON AFFECTIONS OF THE EAR.

DR. THOMAS R. POOLEY, in a paper on this subject, said that probably the first to call attention to the value of the ophthalmoscope in this connection was Dr. Kipp of Newark. One of the cases reported by him was of special interest. It was one of acute purulent inflammation of the middle ear, with double optic neuritis, but without tenderness, swelling, or spontaneous pain in the mastoid process. The patient complained of pain and throbbing in the ear which had lasted for six weeks. The tympanic membrane was of a deep red color, and much swollen. The ophthalmoscope showed the eyes to be entirely normal. A free opening was made in the drum membrane, and the cavity syringed out daily. About two months later, the ophthalmoscope revealed a well marked optic neuritis in both eyes, although vision was not impaired in either eye. The temperature was 99°, pulse 72, and there was no chill. The mastoid was opened and thoroughly cleaned out subsequently, and this was followed by improvement. After a month or two the discharge ceased entirely. The optic neuritis remained stationary for about one week after the operation, and at the end of a few weeks had almost entirely disappeared. She had been kept under observation and had remained in good health, the vision and optic disks being normal.

His own case was one of purulent otitis media occurring in a young boy. He had had otorrhea for many years, and some years previously Wilde's operation had been made at Budapest. When first seen by the speaker, the temperature had been 102.5° and the pulse 128. Wilde's incision was made, and quickly followed by a subsidence of the temperature, but another rise of temperature occurred the next day. Schwarze's operation was then performed, and about a dram of foul, caseous matter removed from the antrum. During the operation, a considerable part of the surface of the dura was exposed in the wound. For twenty days the temperature oscillated between 101.5° and 105.5°, and the patient showed occasional maniacal excitement. At the end of this time, the patient became blind in the right eye and the ophthalmoscope showed optic neuritis on the right side and violent hyperemia on the left. Hemiplegia then developed and soon afterward the patient died. At the necropsy, the vessels of the dura were found to be intensely engorged, and there was a layer of thick, foul-smelling pus which bathed the left hemisphere. The optic nerve was swollen. The cerebellum was normal. A large encapsulated abcess was found in the anterior portion of the occipital lobe on the left side, and around this the brain was softened. It was found that the dura at not been perforated at the mastoid operation.

The following conclusions were drawn: (1) That the ophthalmoscope was valuable in arriving at the diagnosis of cerebral disease, in some instances by confirming the evidence given by other symptoms, in others, by giving the principal, if not the only reliable evidence of brain disease. (2) The intraocular end of the nerve is never inflamed where the disease remains limited to the middle ear and mastoid, but is certain evidence of brain disease. If, therefore, optic neuritis is found, the diagnosis of extension to the brain is certain, whether or not there are other evidences of this condition. (3) The form of optic neuritis is always that seen in affections of the brain, viz.: choked disk—and this may vary from simple evidence of stasis to the pronounced choked disk. In his opinion, the various forms of neuritis described were only different degrees of this particular form of optic neuritis. The presence of optic neuritis was unfortunately no aid in the solution of the problem of determining the localization and nature of the disease. (4) It occurs most frequently in chronic purulent otitis media than in acute cases. In the latter it is very rare. (5) The list of brain lesions in which optic neuritis is observed embraces nearly all the usual lesions—abscess of the brain, meningitis, and sinus thrombosis. (6) The occurrence of optic neuritis in otitis media chronica with implication of the mastoid, and a history of long-standing otorrhea is, by inference, due to a cerebral abscess. (7) The extent to which the presence of slight edema of the optic disk should influence us in determining the operation on the mastoid was an open question, but he thought we might accept Andrews' conclusion, that as the operation, when properly performed, is not dangerous, we may accept edema of the optic disk as an indication for opening the mastoid, with the object at least of establishing free drainage from the middle ear. (8) The existence of optic neuritis as an indication for the more serious operation, such as exploration of the brain for intracranial disease, could only be considered in connection with other symptoms, but so far as it went, it made the presence of intracranial disease more certain.

DR. J. HERBERT CLAIBORNE said that the conclusions presented in the paper covered in a succinct manner nearly all that was known on the subject. Many did not perform the mastoid operation in the manner that Schwarze did. Of this he could speak positively because he had studied at Schwarze's clinic. In none of the cases seen there had there been any symptoms pointing to ocular trouble. In Berlin he had seen for seven weeks an interesting case—one of chronic purulent otitis media. She had suddenly developed a high temperature and delirium, and had died before morning. The autopsy showed that the pus had passed through into the meninges of the brain and had excited a purulent meningitis. It seemed to him that the optic neuritis could hardly be a reliable guide as to the best time to allow the wound to close; the ordinary guide in practice was whether or not the wound was healing properly from the bottom. He doubted whether optic neuritis would prove to be a trustworthy guide to the necessity of operation.

Dr. Pooley said that he did not wish the conclusions to be accepted as entirely his own; they had been intended to represent rather what had been gleaned from the literature of the subject. He felt sure, however, that optic neuritis would be found much more frequently if the physician took the trouble to look for it. The percentage of cases in which the eye is affected in purulent middle ear disease has not yet been determined.

REPORT AND EXHIBITION OF A CASE OF UNUSUAL SPEECH DEFECT.

DR. G. HUDSON MAKUEN of Philadelphia, presented a case of this kind in the person of a young law student. When six months old, this young man had lost the sight of one eye; when seven years old, he had had a severe attack of diphtheria, and another at the age of twelve years; and he had had scarlatina at the age of ten. The purulent otitis media had existed since the scarlatina. In 1893, there had been an acute suppuration of the attic, and aggravation of the old trouble. Adenoid vegetations had been removed on two occasions. There was a marked retraction of the lower jaw, which destroyed the character of the labial sounds, and this could only be overcome by long practice in protruding the lower jaw when speaking. The soft palate was greatly relaxed and was impeded in its action by the adenoid growths. It trying to say "s," instead of the palate rising to the roof of the mouth, it remained down on the tongue, The adenoid thickening in the pharynx was looked upon as the original cause of the defect of the speech, and the patient was carefully instructed as to the best method of securing improved articulation by careful and persistent practice.

DR. H. HOLBROOK CURTIS of New York, exhibited the instrument devised by Professor Oertel of Munich, for viewing the vibration of the vocal cords. The instrument is constructed on the principle of the well-known siren, and is set in motion by an electromotor. If, for example, the siren and the patient are made to sing the same note, say C, there will be 512 vibrations of the vocal cord per second, and the same number of interruptions of the visual field by the siren, and the observer will see that portion of the vocal cord which appears perfectly at rest. By passing slowly from one side of the cord to the other, and properly adjusting the speed of the instrument with reference to the note sung by the patient, the observer can see the nodes and segments of the entire cord. By this instrument, the speaker said, it had been absolutely disproved that sounds are made by the vocal cords coming together, except for a small part posteriorly. With this instrument, the "nodules of attrition" could be seen, and the patient could be taught by a new method to sing in such a way as to remove these nodules inside of a week, even in cases of very long standing. The patient should be given a certain note to sing, and should practise singing this note according to a certain method for hours every day. In this way a very speedy cure of this trouble some disorder among singers could be secured.

Dr. Curtis also exhibited a modification of Ziegel's auroscope.

OTITIS MEDIA SUPPURATIVA WITH AN UNUSUAL PERFORATION OF THE MASTOID.

DR. E. E. HOLT of Portland, Me., reported a case of this kind occurring in a man, forty-five years of age, who had begun to have headache on June 22, 1895. When seen by the speaker on July 30th, there was a perforation on the anterior inferior portion of the membrana tympani through which muco-purulent matter was discharged. He complained at times of pain and tenderness. The ear was treated with cleansing and astringent solutions. There was no tenderness or swelling of the mastoid, but there appeared to be a slight prominence in this region. There had been a very slight rise of temperature at times. After twenty-one days of this treatment, he had decided to chisel away the mastoid, and on doing so he had found the bone extensively necrosed, and pus tracks leading down into the intermuscular spaces in the neck. The speaker deprecated the common practice of dismissing a patient with the simple direction that the ear should be frequently syringed out; it was much safer and better, if the case could not be kept under constant observation, to direct that the ear be kept lightly plugged with clean cotton, and not syringed at all.

THE PRESIDENT said that these cases opening into the digastric fossa were among the most interesting with which we had to deal. He had recently seen a very similar one. Although the temperature had been taken at intervals of two hours, there had been no elevation of temperature. At the first incision, pus was evacuated, and it was found that the interior of the mastoid was entirely broken down. The only symptom of mastoid inflammation in this case was local tenderness and a sinking of the upper and posterior wall. His own experience had been that patients were more apt to infect the auditory canal with cotton than if they left it alone. While it is usually unwise for a patient to syringe out the ear, one of the family could be easily taught to do it properly.

A CONTRIBUTION TO THE STUDY OF LAYNGEAL VERTIGO.

DR. A. C. GETCHELL of Worcester, Mass., in a paper with this title, stated that he had succeeded in collecting forty-one cases. Five of these were over sixty years of age, nine were between fifty and sixty years, thirteen were between forty and fifty years, and the others were still younger. Ten were asthmatic, one was epileptic, and one had an epileptic brother. Loss of consciousness was expressly stated to have occurred in thirty-two cases, and falls in twenty-six. Slight mental confusion was noted in five; dizziness was mentioned in eight cases; true vertigo was mentioned but once. In thirty-three of the cases it was due to violent cough. Tickling or burning sensations about the larynx were mentioned in thirteen cases; congestion of the face was noted in ten; two were reported as pale; bronchial asthma occurred in eight cases. Most of the cases had several attacks, although sometimes at quite long intervals. The treatment had consisted in the internal administration of the bromids, and local measures for the abnormal conditions about the larynx.

The speaker said that Charcot had first described the

disorder and had given it its name, but this certainly did not give a correct notion of the disorder. The average age of the patients was against the theory of its epileptic origin. If the theory of forced expiration were correct, it would seem that obstruction of the circulation should be noticed prior to the attack. The circulatory condition is probably nothing more than an exciting cause in a limited number of cases. Five of the series had nervous temperament. A history of epileptic seizures was not infrequent. It could not be denied that the fundamental pathological fact is an unstable condition of the nervous system. Brown-Sequard's researches showed that the larynx has an intimate nervous connection with the nervous system. The author's conclusions were: (1) That laryngeal vertigo occurred in persons in whom there is an unstable nervous equilibrium; (2) that there was usually some condition of the upper air passages liable to cause glottic spasm; and (3) that severe paroxysmal coughing may cause syncope, but only when there is an existing disorder of the central nervous system.

DR. SARGENT F. SNOW of Syracuse said that he had seen a case of laryngeal vertigo or epilepsy some years ago. A laboring man, about twenty-four years of age, had come to him for examination of the larynx, and had said that he would completely lose consciousness at times, for perhaps thirty seconds. The larynx was found to be markedly congested, the cords were reddened, and he was somewhat hoarse. During the first examination he lost consciousness five or six times as a result of the irritation of the laryngeal mirror. There appeared to be a distinct spasm of the larynx. His physician had been treating him with bromids, but without benefit. This was stopped, and he received treatment directed toward controlling the congestion of the larynx. All his laryngeal symptoms disappeared, and did not return. One member of his family had suffered from epilepsy.

DR. WENDELL C. PHILLIPS of New York said that the only case of this kind that had come under his notice had presented an unusual symptom—a well-marked chronic bronchitis, with bronchorrhea. All the laryngeal attacks had begun with a severe spell of coughing, and then he would fall down and completely lose consciousness for a moment. He had found that treatment of the bronchitis yielded the best results, although the cure was aided by local treatment of the larynx.

DR. R. C. MYLES of New York said that he had seen an interesting case of this kind a few years ago, in a man about fifty years of age. This man was subject to attacks of bronchitis and coughing, and at such times would occasionally suddenly become unconscious for a moment, and then fall. He was a high liver. His diet was somewhat restricted, and the treatment directed to the larynx, and under this a cure was effected. It should be noted that in all cases of death from impaction of a foreign body in the larynx the individual falls unconscious with great suddenness.

DEVIATION OF THE NASAL SEPTUM; OPERATION.

DR. WENDELL C. PHILLIPS of New York, presented a boy who, while playing "shinny," was struck with the stick over the nose. This caused a severe nasal hemorrhage, which subsided without special treatment. Many months later he had been first seen by the speaker. Examination showed almost complete occlusion of both nostrils, as if the blow had caused the septum to be driven back upon itself. Four weeks ago, he broke up the septum completely with the Adams forceps and introduced the perforated cork splints devised by Dr. Berens. These had just been removed and the result was quite satisfactory.

DR. C. W. RICHARDSON of Washington, D, C., said that he had operated upon a number of cases of V-shaped deflections of the septum, but he had found that the septum would drop back into the old position. Since he had used the perforated splints of Dr. Berens, the results had been very good. The reaction from the introduction of these splints usually subsided in three or four days.

DR. DWIGHT L. HUBBARD of New York, said that the great point was not to be in a hurry to remove these corks. He had frequently left them in ten days without any harm. Another point was not to leave out the corks altogether too soon, He had found that relapse had sometimes followed removing them after four weeks, but never if they had been left in for six weeks.

DR. H. H. CURTIS said that he considered this splint the most scientific and useful of the splints devised for this purpose. After doing one of these septum operations recently he had been surprised to find that the patient was a "bleeder." The hemorrhage was stopped by a very light plugging with styptic cotton. He believed that light plugging and pressure with a copper wire at the right spot constituted the best method of checking such hemorrhage,

DR. EWING W. DAY of Pittsburg, said that once while operating under ether he had met with a tremendous arterial hemorrhage after the first incision of the septum, and the patient had nearly lost his life from it. He preferred now to operate under local anesthesia.

DR. PHILLIPS, in closing the discussion, said that Dr. Asch recommended cutting the septum at the point of greatest deflection—near the middle—by means of a specially devised pair of scissors. The trouble in Dr. Day's case was probably that he cut too close to the floor of the nostril. He had seen ulceration and perforation of the septum result from undue pressure brought about by the prolonged use of two splints.

DR. MYLES presented a case for diagnosis; it presented some of the features of

ACTINOMYCOSIS BOVIS.

It had been under observation only a few days. He said that he had seen several cases of true actinomycosis bovis, and most of them had been examined microscopically so that there could be no doubt about the correctness of the diagnosis. They had been cured by extirpation of the growths. The growths appear hard, tough, and leathery, like the lichen on wood.

REPORT OF A CASE OF HEMORRHAGE FROM THE EXTERNAL AUDITORY CANAL,

by DR. C. W. RICHARDSON of Washington, D. C.

The patient was a woman, thirty-six years of age, who had at first hemorrhages lasting for a day or two, and recurring at intervals of a week or more. This continued for a period of six months. In February, 1895, the bleeding became profuse and persistent. It had no reference to the menstrual function. Examination showed no solution of continuity throughout the whole canal, or of the membrana tympani. The Eustachian tube was patulous. Pain was experienced throughout the whole history of the case, particularly in the region supplied by the trigeminus. After several months of observation he had become convinced that the patient was neither hysterical nor a malingerer. The exact source of the hemorrhage could not, however, be determined.

DR. POOLEY referred to a case of hemorrhage from the auditory meatus which at first was puzzling, but it was finally found that the blood issued freely from a perforation in the drum. Further examination showed petechial hemorrhages in different parts of the body, and the diagnosis of scurvy was made. The case terminated fatally, and the necropsy showed the usual conditions found in scurvy, including the petechial hemorrhages into the brain.

THE PRESIDENT said that the tenderness along the trigeminal distribution would seem to indicate that the case reported appeared to partake of the nature of herpes —in other words, that through some interference with the nutrition of the walls of the blood-vessels the hemorrhage occurred. A somewhat similar condition was found among gouty individuals.

DR. RICHARDSON, in closing the discussion, said that the blood had been examined, but with negative result. There was no indication of scurvy in his case, or of the hemorrhagic diathesis, for she had been operated upon previously without the occurrence of unusual hemorrhage.

HYSTERICAL AFFECTIONS OF THE MASTOID.

DR. J. E. SHEPPARD of Brooklyn, read a paper with this title. The first case reported by him was that of a girl, eighteen years of age, in rather poor health, who came to him with the history of deafness for three years, and of pain and tenderness around the right ear for the past three weeks. Bone conduction was better than aerial conduction. Firm pressure could be made over the part without causing pain. The patient was given sodium bromid, and in a few days was well. The second case was that of a young woman, twenty-one years of age, who had fallen down an elevator shaft. Recently she had felt dizzy, and had exhibited a tendency to fall backward to the right side. She complained of pain around the ear. The mastoid region appeared to be tender, but not at all edematous or swollen. A proposition to operate did not lessen her symptoms at all, and for several days he had been in doubt as to the correct diagnosis. Two *séances* of partial hypnosis produced a cure. The third case was a woman, twenty-three years of age, who stated that for the past few months, following a cold, she had suffered from pain in and around the ear, without any discharge. Examination showed no evident cause for the condition, and the diagnosis was made of hysteria, and her attending physician was advised to treat the case by "suggestion." He had been unable to learn the outcome of this case.

DR. RICHARDSON said that not long ago he had been guilty of operating upon a case of this kind. The patient was a young woman, about eighteen years of age, who had been treated six years ago for suppuration of the right ear. When seen again, the ear was once more suppurating, and there was extreme tenderness over the mastoid region. She had become hysterical as the result of grief over the death of her mother. There was no edema or redness over the mastoid, but it was well known that there were cases of serious mastoiditis without the usual signs. After waiting about two weeks, he had opened the mastoid cells, only to find them perfectly normal. The patient was, however, completely cured.

DR. MYLES referred to the case of a young lady in most comfortable circumstances, who had suddenly developed extreme tenderness in the mastoid region. The girl was hysterical, and he had some reason to suspect that she purposely irritated the ear. The girl was greatly pleased with a proposal to open the mastoid, but after consultation this was postponed, and the patient recovered without further treatment.

DR. PHILLIPS recalled a case of recurrent furunculosis of the canal, and finally of severe pain and tenderness in the mastoid. One day, she forgot to remove the articles that she had been introducing surreptitiously into the ear, and examination showed a fragment of a pin and several pieces of finger-nails in the canal.

DR. J. E. NICHOLS said that in one case which he had seen, the mastoid cells were healthy, but the patient had been cured at once by opening them. In another case in which there was an excoriation of the anterior wall of the canal, and in which he suspected that the hemorrhages complained of had been produced by picking this spot with a pin, hypnotic suggestion was only temporarily beneficial, but a proposal to operate was sufficient to effect a cure. It was not at all improbable that there might be some elevation of temperature in these cases, thus still further obscuring the diagnosis, but ordinarily this elevation would be slight.

THE PRESIDENT said that in this discussion nothing had been said about the result of comparing the two sides. In these hysterical cases in which pain was complained of on one side, there was usually as much tenderness on the other side. He recalled a case in which, at each menstrual epoch, there would be a marked edema and tenderness over the mastoid. Such a condition must be looked upon as anglo-neurotic in character.

SECOND DAY—APRIL 18TH.

PHARYNGEAL TUBERCULOSIS.

DR. ROBERT LEVY of Denver, Col., said that he had preserved records of 162 cases of laryngeal tuberculosis. Of this number, 17 showed pharyngeal tuberculosis. Ulceration of the hard palate was the least frequent. The severity and course of this affection depended upon the number and location of the areas affected. When several points of attack develop simultaneously, or there is an ex-

tensive process going on in the lung, or when the posterior wall alone is involved, extension is slow. The coexistence of syphilis he considered to be the most important modifying circumstance. The stages of pharyngeal tuberculosis depended upon the mode of infection. When the infection occurred through the lymph channels, ulceration seemed to be the method of attack; where there was a local invasion, there would be an acute pharyngitis and the development of superficial pin-head tubercles. The diagnosis was not difficult in typical cases. In those cases complicated by syphilis, the character of the ulceration might be puzzling; there would be usually slight pain, and the case would pursue a sluggish course. The finding of tubercle bacilli, the condition of the lungs and the results of treatment would enable one to make the diagnosis. Nitrate of silver, forty grains to the ounce, was useful in the early stage, when the ulcerations were few and small. , Curettage and lactic acid had given him fair satisfaction, but the galvano-cautery had proved to be the best of all the agents he had employed. Cocain spray and iodoform insufflation were valuable for home treatment. When combined with syphilis, his experience was in favor of the use of mercury in small doses rather than potassium iodid—he had been forced to the conclusion that the Colorado climate was unfavorable to pharyngeal tuberculosis. His conclusions were: (1) That pharyngeal tuberculosis occurred in one and a half per cent. of all cases of phthisis; (2) that there were two sources of infection—(*a*) local attack on an abnormal mucous surface, and (*b*) through the lymph channels; and (3) that the severity of the symptoms was modified by the site of the attack and the existence of laryngeal and pulmonary complications and the association with syphilis.

DISEASES AND TREATMENT OF THE NASAL ACCESSORY SINSUES, WITH AN ANALYTICAL REPORT.

DR. ROBERT C. MYLES exhibited some drawings taken in a darkened room in 1893 by means of transillumination. These had been presented to the Academy of Medicine in 1893. In polypoid cases he had entered the sinuses through the nose many times. About two-thirds of the cases of ethmoid disease were due to polypoid disease, and one-third to atrophic rhinitis, non-syphilitic necrosis syphilis and neoplastic growths. At the present time, he had three cases of sphenoidal empyema under treatment, and he had come to the conclusion now that the nose and teeth were about equal as casual factors of antrum disease. The simple irrigation tube and small trocar and canula he considered invaluable aids to diagnosis. Not so much depends upon the pathology as upon the extent of the pathological process. He thought it was the physician's duty in all acute and subacute cases of catarrh to employ either expectant or exploratory treatment. Exploration in antral cases is carried out by irrigation through the natural opening or through a small artificial one. There are hundreds of cases of sinusitis with muco-pus, in which there was no solution of continuity of the membrane. He had operated by almost every method that had been recommended, and all the milder cases had done well. He recalled a case which terminated fatally, in which death might have been averted by the operation suggested which the patient had refused. He had adopted the rule of operating externally in frontal sinus disease when the symptoms were profound, and were not relieved by other methods. In extreme polypoid cases, the ethmoid was rather brittle; it was almost flinty hard in the supperative cases. After removal of the middle turbinated bone it was his practice to drill or gouge an opening into the cells, and cut away as much of the cells as possible. All his cases have been relieved in this way, and some cured. The sphenoid cells were not so difficult to open as many seemed to think. He did not believe curetting the upper and posterior wall of these sinuses was safe. The cells were from one to one and a half inches in depth. He did not agree with the general surgeons that the antrum of Highmore should be treated as other diseased cavities are treated. Curetting often aggravated rather than helped the condition. Where the tooth appears to be the cause of the trouble he advised removal of the tooth, and penetration through the socket into the antrum. This method was so simple and harmless that it should be made a part of the expectant treatment.

DR. PHILLIPS said that he quite agreed with the reader of the paper regarding the etiology of antral disease. He found that the dental profession was very much inclined to follow the teaching that almost all antrum cases were due to some defect in the teeth or in the bone. In his opinion, inflammation of the antrum was not an infrequent disease, but suppurative inflammation of the antrum was more rare, He did not think it was necessary to remove a tooth if the teeth were perfectly sound; it was better to penetrate through the canine fossa. A few weeks ago he had seen a man who gave every indication of suppurative disease of the antrum. By transillumination he had found that there was a bright area on the right side, and a dark shadow on the left side. Some observers claimed that transillumination was unsatisfactory, but the reason usually was that it was not properly performed. The source of the illumination should be placed in the mouth, and the observer should note the character of the illumination beneath the eye. He would be unwilling to operate in a case with darkness on one side and light on the other, unless there were other symptoms of antrum disease. Transillumination is a useful aid, but should not be considered in itself sufficient ground for a positive diagnosis. He had found that by percussing over the the antrum in this patient tenderness had been elicited on the right side. Cocain cataphoresis was used in this case, with a current of fifteen volts. A free opening was made into the antrum and, according to the statement of the man, the operation was painless. Last summer he had seen a man who had rapidly developed an acute inflammation in the frontal sinus, following upon a violent insufflation of powder on that side. This insufflation had been done in one of the advertising quack catarrh cures in this city. An abscess suddenly developed. He had followed Dr. Myles' plan of making the incision. As soon as the opening was sufficiently large, the polypi forced themselves out through the opening that he had

made in the frontal sinus. He removed nearly half an ounce of polypoid material from the sinus. The man had been advised to come back for a second curetting, but this he had positively refused to do and, hence, it was not improbable that there would be a relapse. Recently he had been operating upon a colored cadaver, and had been surprised at the extreme smallness of the sinus.

DR. G. HUDSON MAKUEN said that a few weeks ago he had reported a case of unusual alveolar abscess with antral complications. The patient had complained first of pain around the second molar tooth in the upper jaw on the right side. After two or three days a slight sero-purulent discharge made its appearance between the gum and the tooth. A dentist who saw the case expressed the opinion that the case was one of alveolar abscess. On opening the tooth he found it apparently healthy. The tooth was devitalized and the pulp removed, but without benefit to the patient. Shortly after this, while probing, the dentist passed his probe into the antrum. On removing the tooth, a small pus sac was found, midway on the tooth. This sac was half an inch from any infection by way of the mouth, and certainly no infection could have come through the antrum. His experience had been that when a large opening was made at the floor of the antrum, the cavity did not drain through this opening unless there was an obstruction of the natural opening. He suspected that the movements of respiration caused a suction through the nose, and thus accounted for drainage taking place against the action of gravity.

DR. E. E. HOLT said he desired to express his high admiration of this paper from the standpoint of the ophthalmologist and otologist. In cases of orbital cellulitis, one was often brought in contact with the antrum of Highmore.

DR. DAY said that he had found quite a number of cases in which transillumination showed a shadow on both sides, and sometimes on one side, without any other indication of antrum disease. He had, therefore, become somewhat skeptical as to the value of transillumination in diagnosis.

DR. MYLES, in closing the discussion, said that there were thousands of people in this country who had been suffering for years from catarrh, and from antral disease, and yet they had been treated by very competent physicians. The remark that had been made about the smallness of the frontal sinus reminded him of the fact that some colored people seem to have no frontal sinus, or only a very small one. It was an easy matter in such cases inadvertently to make an opening directly into the cranial cavity while operating. In his experience, most the cavities of the nose appeared to drain by a to and fro motion of the air, due to the respiratory movements. Regarding the matter of transillumination, the speaker said that hundreds of people presented a dark shadow beneath the eyes, but in almost any case the shadow could be made to disappear by the use of sufficiently powerful illumination. There were many drawbacks to transillumination, but it was nevertheless a very valuable aid to diagnosis, and one which should not be neglected.

ACUTE OTITIS MEDIA AS A COMPLICATION OF TYPHOID FEVER.

DR. D. A. HENGST of Pittsburg read a paper on this subject. He said that when we considered the convenient pathway for microbes through the Eustachian tube to the ear, it was not surprising that this affection was so common. As a result of a collective investigation that he had made, he had received reports of 1228 cases of typhoid fever, 575 of which were from private practice, and 653 were hospital cases. There were 11 cases of otitis media reported among the former number, and 17 from the latter. Out of 389 cases of typhoid fever occurring in the Johns Hopkins Hospital, it had been reported that there were 8 of acute otitis media. It most commonly developed from the end of the second to the fourth week, or at the time when the capillary circulation was sluggish and the patient in a delirious condition. He had not been able to gather statistics regarding the frequency of mastoid complication. In connection with the question of the influence of quinin on the production of otitis media, it should be noted that one physician who reported 175 cases of typhoid fever, with 5 of otitis media, stated that it was his practice to use large doses of quinin during the stage of hyperpyrexia. The most usual method of extension was from the mouth or naso-pharynx into the ear. The chief symptoms of this complication were deep-seated pain and tenderness on pressure below the auricle, a feeling of pulsation and tinnitus. In some cases of typhoid fever there is a severe neuralgic pain in the ear, but there is no deep-seated pain below the auricle, and the accompanying changes observed on examination with a speculum are not present. If seen early, or in the hyperemic stage, leeches should be applied to the tragus, and the instillation of a warm solution of boric acid will often be followed by prompt relief. The ear should be frequently cleansed, and as soon as bulging is observed, the membrane should be incised. The parts should be kept thoroughly aseptic afterward. In nearly all cases of otitis media complicating typhoid fever, good hearing has been the result.

THE PRESIDENT said that he certainly thought acute inflammation of the middle ear was a very rare complication of typhoid fever. He did not believe in the use of moist heat in the early stage of the inflammation, because this tended to break down tissue. In his experience, dry heat relieved the pain quite as well as moist heat, and was free from the objection just stated. He would also favor a resort to incision of the drum membrane before the membrane bulged, as the object was largely to secure depletion. A great variety of germs appeared to be responsible for such an inflammation of the middle ear.

ULCERATION OF THE NASAL SEPTUM.

DR. T. C. CHRISTY of Pittsburg read a paper with this title. He said that the onset of the trouble was usually attributed to taking cold. It was ushered in by pain over the frontal region, corresponding to the obstructed nares, and by pain in one or both ears. There were usually signs of acute inflammation over the obstructed nares. In the majority of cases, the lesion originated on the septum, and was communicated to the other parts by the swollen

soft tissues. In one case there was inflammation of the septal cartilage. In no case was there destruction of the hard palate, as so frequently occurred when the septum nasi was involved. The galvano-cautery is not a valuable agent in the treatment of lesions of this character. Tubercular ulcers are, as a rule, secondary, slow in development, and painful. Malignant ulcerations are painful, and often have an inflammatory appearance. His observations had led to the conclusion that the prolonged residence in a high altitude was, in some instances, pernicious to the delicate mucous covering of the septum nasi.

DR. ROBERT LEVY said that he must take exception to the statement that prolonged residence in high altitudes was pernicious to the nasal mucous membrane. In an experience of ten or twelve years in a region situated over one mile above the level of the sea, drying, crusting, and annoying nasal symptoms had been observed only among those who had recently arrived. After a time Nature met the demand for rapid evaporation of water at such high altitudes, but at first these individuals usually suffered from dryness and excoriation from picking the dried secretions.

DR. ARTHUR G. ROOT of Albany said that he knew of no disease which was so amenable to treatment as syphilis, whether in the nose or in any other part of the body. He was firmly convinced that many physicians were disappointed with the results or their anti-specific treatment because they expected marvelous benefit from simply giving of these remedies without taking into account the general condition of the patient, and what could be obtained by careful hygiene and good nourishment. Some of these patients would do better for a time if the anti-specific remedies were suspended and reliance placed entirely in hygiene and diet.

DR. SNOW said that in these cases of tertiary syphilis, much of the trouble in managing the case was due to insisting upon the use of mercurials instead of trusting to potassium iodid. In cases of ulceration of the septum, not due to syphilis, he had found deliquesced chromic acid acted admirably.

DR. HOLT said that he desired to heartily indorse what had been said by Dr. Root about the hygenic treatment of syphilitics. In many cases he had gotten better results from sodium iodid than from potassium iodid, the former being better tolerated by the stomach.

DR. W. B. JOHNSON of Paterson, N. J., thought it was somewhat dangerous to undertake to feed up a syphilitic patient and suspend medication, while the disease was actively engaged in dragging him down. He was positive that the combination of potassium iodid and mercury often acted better than iodid alone.

DR. MAKUEN said that in the past year he had had two such cases in which the diagnosis had been rather difficult. The first was a young women in whom there was no suspicion of syphilis. A pathologist reported that the case was one of round cell sarcoma, but the operation having been unavoidably delayed, the patient was put on anti-syphilitic treatment, and was speedily cured. It another case, that of a man who denied syphilis, he was still in doubt, but was trying anti-specific remedies.

DR. LEVY said that he was reminded of a case in which two microscopists had independently examined the case, and had reported it to be one of round cell sarcoma. This patient had had many of the symptoms of a malignant growth, yet she was speedily cured by anti-syphilitic treatment.

DR. CHRISTY said that the object of his paper was to emphasize the importance of preserving, in every way possible, the integrity of the mucous membrane of the nose in all cases.

THE MASTOID AND INTRACRANIAL COMPLICATIONS OF MIDDLE-EAR SUPPURATION.

DR. EDWARD B. DENCH of New York, read a paper with this title. In describing the operative treatment of mastoid disease, he said that he considered that a mastoid operation, done with proper attention to technic, was perfectly justifiable as an exploratory procedure, and was devoid of danger. He had operated upon 105 cases of mastoid disease, of which five had died. Three of these were cases in which meningitis was the cause of death, and had existed at the time of the operation. The other two were due to prior cerebral abscess. In this large number of cases, therefore, not a single death could be attributed to the operation. An absolutely perfect asepsis should be secured, as much care being taken as in preparing for an intraperitoneal or an intracranial operation. The incision was ordinarily made about half an inch beyond the auricular attachment, but personally he preferred to begin it at the tip of the mastoid, and carry it toward the insertion of the mastoid, leaving a space of about one-eighth of an inch. The incision should be carried up toward the superior part of the auricle. Within the triangular space bounded by two tangents, one drawn to the superior wall, and the other drawn to the posterior wall, and the curvilinear line of the meatus, lay the point of safety. Drilling should be abandoned, and the opening into the bone made by a chisel. So far as he knew, Dr. E. Gruening had been the first to lay down definite rules for the systematic opening of the mastoid. The first objective point in the operation should be the mastoid antrum. After a probe had been passed from the antrum into the middle ear, it was safe to remove the tip of the mastoid or take what further steps seemed necessary. The *additus ad antrum* should be carefully curetted, for otherwise the discharge is apt to persist. If the incision were made in the usual place, the ear was apt to remain for a long time pushed forward, and deformed, which was not the case when the incision was made as he had recommended. The bony cavity alone should be packed, the external wound being left free from the dressing. If there were no pain or elevation of temperature, he often allowed the first dressing to remain unchanged for five or seven days. If the lateral sinus should be opened, the hemorrhage could be easily controlled by firm packing with iodoform gauze.

The speaker also reported a successful case of operation in a patient having leptomeningitis. An incision had been made from the tip of the mastoid over the ear to the external angular probes of the frontal bone. He had then

entered the middle cranial cavity through the thin portion of the squamous bone. There was a distinct meningitis present at this time. There was no purulent accumulation found in the region of the roof of the tympanum or the lateral sinus. The wound was packed, except in the region of the tympanic roof. The man had had no further trouble, and recovery had been prompt. In doing an exploratory operation, an ample cutaneous incision should be made over the external meatus.

DR. R. C. MYLES said that during the last few years he had been studying this subject, and had operated between one and two hundred times on the cadaver. The points made regarding the method of making the incision and reaching the antrum were particularly valuable. He raised the question as to whether we should chisel at the upper level of the osseous margin or at the center. His plan was not to destroy the upper posterior part, but to expose the cells just posterior to the osseous canal, and extend the opening in a spiral manner upward, inward, and forward through the antrum into the attic. The approach to the lateral sinus could be usually determined by the great hardness of the bone and the bluish color of the part.

DR. W. B. JOHNSON said that there were times when it was very difficult to secure absolute asepsis. He had been greatly interested in the case of leptomeningitis which had recovered after operation, yet he felt that it would be extremely rare for recovery to follow in cases in which meningitis or cerebral abscess existed prior to the operation.

DR. RICHARD FROTHINGHAM of New York, remarked that some very good operators still used the drill.

DR. DENCH, in closing the discussion, said that some good operators still used the burr, but this was very different from the old hand-drill to which he had referred.

REVIEWS.

THE DISEASES OF CHILDREN. By J. LEWIS SMITH, M.D., Clinical Professor of Diseases of Children, Bellevue Hospital Medical College, etc. Eighth edition. Pp. 987, with 273 illustration and 4 plates. New York and Philadelphia: Lea Bros. & Co.

THE general character and scope of this work is so well known that it will be necessary only to refer to the changes which have been made in this new edition. The work has been considerably enlarged, and several entirely new chapters appear. On page 27 are interesting tables concerning the temperature, pulse, and respiration of healthy infants, which are a valuable addition to our knowledge upon these subjects. It is striking that so slight a difference was found between the rectal and the axillary temperatures of early infancy, this being only 0.2° F., and even during the second year it is only a little over 0.5° F.

The early chapters upon general subjects appear practically unchanged.

The article on diphtheria contains a number of new pages, and is brought down fairly to date. The author might, with propriety, have omitted more of the earlier pages of this article. Concerning antitoxin he speaks in guarded language, and one is led to believe that he is not yet convinced of its value. In concluding his paragraph upon this subject, he says: "It is seen that statistics thus far are favorable for the antitoxin treatment, but it must be recollected that the type of the microbe diseases frequently changes, so that the experience of several years is often necessary in order to determine the full value of a remedy."

Among the new articles, we note a chapter upon cretinism. A whole section has been added upon diseases of the blood, contributed by the late Dr. F. M. Warner, and another section upon the diseases of the heart and circulation. All of these chapters add materially to the value of the book.

The principal addition to the work, however, consists in the introduction of chapters by Stephen Smith, M.D., upon the surgical diseases of children. These relate largely to operations, and it is really questionable whether anything is gained by adding them to the text-book. The illustrations are very familiar, and most of them are found in text-books upon general surgery. There seems to us to be no special justification for a full description of such an operation as that for strangulated hernia, for instance, with cuts of instruments employed, in a work upon diseases of children. After looking over these surgical additions, it must be confessed we would have been better pleased if the book had been kept a medical one.

Many illustrations relating to medical subjects have been introduced which add materially to the elucidation of the text.

Like its predecessors, the general make-up of the book is exceedingly satisfactory; the paper and type are all that could be desired, and the new edition is likely to hold its own among the leading text-books on Pediatrics for the American student.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE SIXTEEN DAYS ENDED MAY 31, 1896.

BOARDS CONVENED.

Board convened to meet in New York City, May 27, 1896, for the physical examination of candidates for appointment in revenue cutter service. Surgeon W. A. Wheeler, chairman, Passed Sssistant Surgeon J. H. White, recorder, May 25, 1896.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 6, 1896.

June 2.—VON WEDEKIND, L. L., surgeon, ordered to the Naval Academy.

June 3.—SIEGFRIED, C. A., surgeon, detached from the "Columbia" and ordered to the "Massachusetts."

June 3.—DERR, E. Z., surgeon, detached from the "Raleigh" and ordered to the "Columbia."

June 3.—BEYER, H. G., surgeon, detached from the Naval Academy June 5, and ordered to the "Raleigh" June 6.

June 4.—GUEST, M. S., passed assistant surgeon, detached from the "Constellation" June 8, and ordered to the "Massachusetts" June 10.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXIX. NEW YORK, SATURDAY, JULY 11, 1896. NO. 2.

ORIGINAL ARTICLES.

NOTES ON INGUINO-SCROTAL CYSTS.

BY THOMAS H. MANLEY, M.D.,
OF NEW YORK.

PERHAPS there is no class of lesions, attended with an intumescence of structure, so localized and easily defined by both inspection and touch, in which, through want of a correct appreciation of the underlying pathology, so many errors are committed in diagnosis as in scrotal swellings. Cystocele of the cord, which was being regularly treated by a truss, to the injury and great discomfort of the patient, has come under my notice more than once. This, when advancing far down into the scrotum, has often been tapped and drained, under the supposition that a hydrocele existed, while, as a matter of fact, the mass was entirely outside the *tunica vaginalis*. A serous cyst had simply been evacuated.

During the month of December last, a case came under my care in which the first physician called had ordered methodical poulticing of the scrotum, for "orchitis." The second practitioner who saw the case, recognized from the grave constitutional disturbances that there was another trouble. I found extensive urinary infiltration, with impending gangrene of the scrotum. Perineal urethrotomy, with free drainage, now availed nothing, the patient sinking from blood-poisoning, some days later.[1]

In June, 1894, a letter-carrier came under my care, suffering from a great enlargement of the left testis. When first seen, the scrotum had been repeatedly painted with iodin tincture, for supposed orchitis. Examination and subsequent operation proved the case to be one of primary sarcoma of the testis, involving the spermatic cord and spreading far up into the retroperitoneal lymphatics.

In the summer of 1892, a case entered my service, which was supposed to be an abscess of the scrotum. The pouch had attained a massive volume, being red, edematous, and sensitive. A minute black speck indicated a point at which the tumor must soon burst. The constitutional symptoms were most pronounced, but what first attracted my notice was the persistent fecal vomiting, with a history that his bowels had been locked for six days, and that he had suffered the greatest agony from "cramps." Poultices over the scrotum and the free use of morphin had been the basis of treatment. A free incision exposed four inches of rotten intestine and the sac distended with feces. He died the same day.

Some years ago, a young woman came under my care, who for three days had been treated for a bubo in her right groin. Her former history was rather indefinite. She, however, had had luetic disease, hence had been freely plied with specific treatment and topical applications. But symptoms of strangulation were unequivocal. Operation revealed the trouble to be an old epiplocele, down beside which a knuckle of intestine had slipped and was nipped. Her recovery was uneventful after kelotomy.

Sero-cystic or myxomatous masses, neoplastic or adventitious, are common in the male infant along the funo-testicular tract, and are occasionally seen in the terminal segment of the unclosed diverticulum, known as Nuck's canal in the female. In either instance the tendency is to mistake them for hernia and apply a truss for the cure of an infirmity that never existed.

On the 30th of March, 1896, a boy, aged four years, was brought to me for the radical operation for hernia. On examination there were so many complex features in the case that I was somewhat undecided whether there was a simple cyst present or a cyst complicated with hernia. He had been treated off and on with a truss for two years, but latterly, the pain it provoked was so great that it had to be discarded. On free incision, a thick, tough membranous bag was reached, intimately adherent to the elements of the cord. This was enucleated, when its pedicle was traced up the inguinal canal to the inner-ring, ligated and divided. It contained sero-myxomatous material. No trace of hernia was present.

A knowledge of the diversified pathological elements which enter into the composition of these inguino-scrotal tumors, opens the way to a correct interpretation of their manifestations and diagnosis. In the young their tendency is toward spontaneous cure, though after adult years are attained, radical surgical measures, in appropriate cases, are at once the safest and most permanent in results. In order, however, that we may understand the various types of disease present, a subdivision or grouping is necessary. In making a classification of inguino-scrotal tumors or enlargements, my purpose will be rather to group them, from a clinical than a strictly anatomical or path-

[1] This case was reported in detail in *Atlanta Med. Monthly* for April, 1896.

ological standpoint, entering with any degree of fulness, only upon cystic disease and vaginal hydrocele.

1. Cystic disease of the spermatic-cord, round ligament, or testis ; with hernia or without it, in the young.

2. Hydrocele—Effusion into the tunica-vaginalis testis. Cysts of epididymis and cord in adults. Simple and complicated.

3. Tumors of the testis—Infectious and malignant.

4. Scrotal enlargement from urinary infiltration.

5. Circocele and Varicocele.

The formation of cysts in the external genital structures is encountered with the greatest frequency at the two extremes of life. In the infant male we find cystic bodies in varying situations from the point where the various structures emerge at the internal ring to the point low down where the fascia spermatica spreads out, to overlap the vas deferens as it leaves the head of the epididymis. They are of variable dimensions, and firm to the touch. Cystic formations in the spermatic-cord or head of the testis are clinically allied with hydrocele, though pathologically different in many important particulars. It is important to be familiar with them, inasmuch as when they develop within the inguinal, or the canal of Nuck, they present many features similar to hernia, and when located in the lower segment of the spermatic-cord or the head of the epididymis, they may be difficult to differentiate from hydrocele. It is important to do this, because, their treatment must be widely different from hydrocele. Cystic disease in this situation, of the neoplastic variety, is of two kinds; one, the simplest and most benign, is primary and uncomplicated ; the other is heterogenous in structure with formations attendant as a degenerative change in various infectious, specific, or malignant diseases of the testis or epididymis. Only the first variety can be considered here.

As they are usually painless in the beginning, it is only when they have attained considerable volume, drag on the cord, or produce painful pressure, that patients become aware of their presence. In all cases this growth commences above the testis. A knowledge of this fact would greatly aid in diagnosis, if the patient were seen early. As it is, however, no reliable information can often be derived on this point. Until recent years they were generally confounded with, and treated as hydroceles. No free dissection of them was permissible, and then nothing more than the common, unsatisfactory, and not infrequently mischievous, tapping was resorted to for their relief or cure. Like hydrocele they never, when large, undergo spontaneous cure in the adult, but produce serious degenerative effects on the genital apparatus by pressure. A close etiological relation seems to exist between these neoplasmata and those so commonly found in the female pelvic organs.

The pathology of these masses is not clear, though we may infer from their anatomical elements and their mode of development, that their occurence is attributable mainly, to two independent factors. It is probable that these distinctly different sources first led Paget to group them in separate divisions. The first he designates "sacculations," being retentions in obstructed canals or tubes, and the second, after Rokitansky and Simon, he sets down as "autogenous cysts," they being dependent on proliferation of the primary anatomical elements of which the parts are composed, and from which they grow. Virchow and Duchesne on the contrary classed them all as hygromata, or serous tumors succeeding dilated passages. Senn, makes no special classification of these formations, only grouping serous cysts of every description into two classes, within the first of which this variety would come.

The views of Davis[1] on the complex character of these strike one as sound and sensible. He says: "Their origin is more or less obscure. It is comparatively rare for them to be simple; they are more often complex and it may be difficult to say to which class they belong," and he adds most truly, that "there seems to be an exaggerated opinion prevalent of our ability by the microscope alone to determine the character of the growth." The author, with most commendable emphasis, calls into question the use of the microscope as a sole reliance in their diagnosis.

Barbè named them *Hydrocele enkystiques du Cord Spermatique.* Symme applied a somewhat similar term to those in the infant. Jourdan,[2] describes, at length, several types of these in the adult. Clements[3] of Dublin, and Moxon of England, set them down as hydrocele of the spermatic-cord; others again regard them as cystic tumors, or spermatoceles. Another author[4] describes certain cysts here of a rheumatic origin.

The pathological anatomy of these cysts has

[4] Deux Kystes Rheumatismaux du Cord Spermatique. *Jour. De l'Anat, Path.*, 1885, iv, p 233.

attracted the attention of many of our most noted investigators, though their conclusions are discordant as to their origin. Cruveilhier, in his atlas on morbid anatomy, exhibits several cases of imperfect closure of the *processus vaginalis* throughout its entire length; in some, the canal being closed in four or more places by fibrous bands. Le Dran, Meckel, Bergman, and Scarpa, report many similar dissections in the newborn. Curling, in his large experience, mentioned several similar conditions, and quotes from Gosselin and Richet descriptions of cases of serous cavities along the cord.

In the opinion of Terrillon many of these serous formations start from the remains or vestiges of serous tissue, lying latent and unabsorbed, which, later in life, through the influence of cold or irritation, furnish the fluid necessary for distention. The remains of the Wolffian bodies or the organs of Geraldes, in the neighborhood of the epididymis, produce within the scrotum a similar condition. M. Duplay,[1] in an exhaustive review on the subject, was inclined also to the view that they depended on the residuary elements of the serosa and Wolffian bodies. De Mieux,[2] later, supported this theory, somewhat modified, to agree with Colnheim's law of neoplastic growths. According to Monod and Terrillon:[3] "Encysted hydrocele of the cord, and cysts of the cord, are those liquid or semi-liquid masses, seated along the spermatic-cord, but independent of the epididymis or testis." They are, as a rule, lined by flat epithelium, have a thin, transparent investment, and are not commonly adherent to adjacent parts. Their volume varies. These tumors are mobile and transparent, and seldom attain a considerable size. Sometimes, they are lodged entirely within the inguinal canal, and may be mistaken for herniæ, or they are more or less movable. They may be accompanied by a hernia, acquired, infantile, or congenital, or a retained testis. Routier and Gosselin[4] have recorded cases, in which blood was found in their interior, after a trauma. When complicating a hernia they occupy the most diverse relations to the viscera. Their contents differ widely in their physical, chemical, and histological characters. In some, an opalescent fluid containing spermatozoids, is evacuated. Many such cases have been reported by Liegegard, Broca, and Robin.[5] Duplay designated them: "peritoneo-funicular hydrocele;" in contradistinction to the "vagino-peritoneo-hydrocele," in which latter the fluid extends into the cavity of the tunica vaginalis.

Although the greater number of these cystomata are formed in the myxomatous elements of the cord, some few are found to spring from the epididymis, and hence, like hydrocele, begin to enlarge from below. According to Broca, Liston and Velpeau, in 1843, first discovered spermatozoids in the fluid elements of these cysts.[1] Gosselin noticed that they were the most liable to appear at that epoch in life when the normal function of the secretion began to decline, a phenomena not altogether unlike the cystic involution of the mammary gland in the female at middle life. How these tumors may originally form, or from what precise anatomical elements they first commence to grow probably must remain largely a matter of speculation. Although the clinical fact is that they are in some manner dependent on degenerative changes perhaps influenced in their incipiency and ulterior course by heredity, the constitution of the patient, or his occupation and habits.

After their growth has begun their advance is attended by all those changes in adjacent parts which we observe in the evolution and advance of any benign formation. As their walls encroach on neighboring tissues, their most vulnerable histological elements give way and disappear by absorption. Those growths arising from the epididymis, it will be observed, are often within the *tunica-vaginalis*, their presence producing a moderate serous *vaginitis-scroti* maintaining an uninterrupted pressure on the nude, defenseless testis; in which event, we may have one fluid bag within another. As the greater part of the hilum of the epididymis is lodged outside the tunica-vaginalis, when sperm-elements are found in hydrocele it has been supposed that they had become intermixed there, in consequence of a cyst of the epididymis having ruptured into the cavity of the *tunica-vaginalis*.

The origin of these growths in the epididymis has been explained variously by different authors. With some it is believed that they develop in consequence of a dilatation of the tubular coils of the epididymis. Their anatomical elements would lend some support to this theory. The inner layer of these tumors, in the greater number, is composed like the normal canals of the epididymis of stratified epithelium, and the admixture of spermatozoids would imply some direct connection

with the seminiferous ducts. Monod has made a careful study of this subject and the anatomical elements of the cystic structures. In order to determine the relation of the tumor to the epididymis, he has injected mercury of the temperature of the body directly into the gland elements, but in no instance did he find any pass into the tumor.

Follin[1] has demonstrated that the *debris* of the Wolffian body in the female is represented by the body of Rosenmuller in the male, or the so-called hydatids of Morgagni, which form a row of bud-like projections on the head of the epididymis. From the vestiges of fetal remains, in his opinion, we may expect that many of these cysts advanced in this direction, especially as the capsule is thinner in this situation. In those taking this direction—the extra-vaginal route—we will find them attaining the greatest volume.

In one of my own cases, a sailor of fifty years, I removed, preliminary to decortication, twenty-six ounces of fluid. Stanley reports one as containing 1600 grams, and Curling one, having within the sac 2000 grams. The walls of these cysts vary in thickness and, as a rule, are intimately adherent to all the elements of the spermatic-cord, especially the efferent vessels of the testis. The color and consistence of the contained fluid varies greatly. Spermatozoids are not constant. In recent, small-sized, simple cysts, the fluid is opalescent and slightly mucoid. These latter, generally contain spermatozoids; but in the larger, more chronic, which are multilocular, degenerative changes have destroyed the germ-cells and various phases of tissue metamorphosis are encountered in their contents the investing membrane and neighboring tissues. These hygromata in serous cysts of the epididymis are seldom witnessed of such volume as to be readily recognized or differentiated. Terrillon said of them, that from the standpoint of the anatomist, they were commonly seen, but clinically, they were comparatively rare. Hochenogg, Professor Albert's assistant, at Vienna, in the examination of 6000 surgical cases coming to the clinic, met with but three cases. During the three previous years antedating the period when these statistics were taken, in a larger number of patients none whatever were found.

From what can be gathered from the scattering cases reported and those whose opportunities for observing these genital cysts are fairly large, it may be affirmed that those which lie along the course of the inguinal canal, arise either through an occlusion of the *processus-vaginalis*, or a neoplastic formation. Those in the spermatic-cord are the most common. The next in order of frequency, are those which rise at the hilum of the epididymis, directly from its capsule or parenchyma, and are extra-vaginal. Those are most rare and least in volume which bud from the head of the epididymis and are lodged side by side with the testis, within the *tunica-vaginalis*.

TOO MUCH AND TOO LITTLE HAIR.[1]

By GEORGE THOMAS JACKSON, M.D.,
OF NEW YORK;
PROFESSOR OF DERMATOLOGY IN THE WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY; AND IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF VERMONT.

It is possible to have too much of even a good thing, and therefore one can have too much hair, especially when that *one* is a woman. It is of facial hirsuties in women that I would speak this evening. We are not now concerned with any other form of too much hair, and will say nothing of those long beards that are some mens' pride, which they can tie in a knot, and put in their pockets, nor of those freaks of dog-faced men, nor of anomalies of hair growth as to time, such as puberal hair occurring at an early age. In the first part of my paper I shall confine myself to a study of the etiology and treatment of hirsuties in women. Then by way of contrast I shall say something about loss of hair.

General impressions are often misleading, while a study of one's case-book is instructive. It was with the wish to find out what my cases of superfluous hair in women had to teach me that I have studied the first one hundred cases occurring in my private practice. As the results were of interest to me, I venture to give them, hoping that they will not fail to be of interest to you also. The cases were taken as they came, and were in no way selected. As would naturally occur, eighty-two of the women were of the mixed race that we call American, as we have no term for a native of the United States other than this. Fourteen of them were Hebrews, though born in the United States. The Jews so rarely intermarry with the Christians that their race is comparatively pure, and worthy to be placed in a special class. Two women were Germans; one was an Irish woman; and one was a Welsh woman. Fifty-eight of the cases were in single women, and forty-two were married or widows.

In ninety-seven cases the age at which the hair first showed itself was noted. The earliest age re-

[1] Read before the Detroit Medical and Library Association, April 6, 1896.

corded was thirteen years, and there was only one who said that she was over fifty when the growth began. There were eleven cases that began at the eighteenth year, and that was the largest number for any one year. A woman passes through certain more or less well-defined periods in her life, determined by her menstrual history. My figures studied in relation to these periods are interesting. They are as follows:

Hypertrichosis began	betw.	the	13th	and	15th	year	incl.	in	3	cases.
"	"	"	15th	"	20th	"	"	"	29	"
"	"	"	20th	"	30th	"	"	"	38	"
"	"	"	30th	"	40th	"	"	"	17	"
"	"	"	40th	"	50th	"	"	"	9	"
"	"			at over	50th	"	"	"	1	case.

We thus find that in seventy of the cases the age at beginning was under thirty.

There is a general impression that there is a connection between the growth of hair on the face in women and disorders of the reproductive organs. My notes show uterine or menstrual disorders were found in but four of the married, and in but nine of the unmarried women. Of the married women ten had no children, seven had one child each, and seventeen had two or more children. As to the special symptoms pointing to disorders of the reproductive organs amenorrhea was found in two cases; dysmenorrhea in four cases; irregular menstrution in three cases; uterine displacements in two cases. The menopause had occurred in eight cases.

Of the one hundred women, sixteen were decided brunettes, and six were decided blondes. The rest were of the medium complexion, that is by far the most common.

In fifty-five cases there was a strong family tendency to hirsuties, as is shown by the following table:

A history of facial hirsuties	In	mother					in	14	cases.
"	"	"	"	"	"	"	and grandmother	"	2	"
"	"	"	"	"	"	"	" mater'nl aunt	"	3	"
"	"	"	"	"	"	"	mat. aunt and sister	"	1	"
"	"	"	"	"	"	"	and sisters	"	3	"
"	"	"	"	"	"	"	sisters and daughter	"	1	"
"	"	"	"	"	"	"	and paternal aunt	"	1	"
"	"	"	"	"	"	"	and others of family	"	1	"
"	"	"	"	"	"		maternal aunt	"	5	"
"	"	"	"	"	"		paternal "	"	2	"
"	"	"	"	"	"	patrnl. aunt and anc'st'rs		"	2	"
"	"	"	"	"	"	patrnl. aunt and daught'r		"	1	"
"	"	"	"	"	"	sisters of patient		"	13	"
"	"	"	"	"	"	sisters and maternl. cousin		"	1	"
"	"	"	"	"	"	women, both sides family		"	5	"

In twelve cases it was said that the patient resembled in her general physique the father. In three of these cases there was also a history of other female relatives having had facial hirsuties, leaving nine cases in which only the paternal form of heredity manifested itself. But very few of my cases showed other evidences of masculinity, such as depth of voice, or coarseness of figure, or manner, greater than was to be found in women of their own grade of life.

The upper lip was affected alone in fourteen cases. The upper lip and chin were affected at the same time in thirty-six cases. The chin was affected alone in five cases. The chin and cheeks were affected together in eight cases. The upper lip, chin, and cheeks were all affected in twenty-three cases. The hair on the whole body was unusually developed in two cases. There were coarse hairs on the chest in two cases. In the other ten cases the location of the growth was not noted. In no case was there any hair on the lower lip except a very few, usually not very coarse ones, just under the middle of the border of the hp.

The greatest number of hairs I have ever removed from one patient is 12,905 in the course of several years, the patient being a young woman who had an unusually heavy growth of hair. Of course this number is not by any means made up exclusively of new hairs, but includes many returns of hairs that had been removed. In eleven cases I have removed 1500 hairs and over, and all of these women were under thirty years of age, and the highest numbers have always been found in the patients in whom the growth began before the twentieth year.

It does not seem to me that we are justified in drawing any special inference from the fact that eighty-two per cent. of the cases were Americans. That would naturally follow because the data were gathered in an American city. It does seem to me significant that fourteen per cent. of them were Hebrews, because my practice is not especially among the Hebrews. We would expect, however, that women with the dark skin and hair of this race would have a tendency to hirsuties. Nor can we draw any inference from the civil condition of the patients. Among the fifty-eight unmarried women were a number who were so young they would hardly be expected to be married, and if these were thrown out, the number of the married and unmarried would be about the same.

It is a most striking fact that about one-third of the cases occurred before the twentieth year, and seventy per cent. of them occurred before the thirtieth year. This, it seems to me, points very strongly to the inference that the growth of facial hair in women is analogous to what occurs in men, that is, it begins at about the age of puberty and during early womanhood. It is, therefore, an inborn peculiarity, an inherent condition of the make-up of the skin, just as ichthyosis is in some people. That only ten per cent. of the cases developed after the fortieth year seems to show how comparatively little the cessation of menstruation has to do with the growth of the hair. It may well be that my statistics are as

misleading as many statistics are, and that it is rather because young women seek relief from their misfortune that the number of them is so large, than that they really are so much more prone to have hair on the face.

The number of women with disorders of the reproductive organs was no greater than would be found among any other one hundred women, only thirteen giving any account of them. Of the forty-two married women or widows, I have notes as to the child-bearing capacity in but thirty-four. I must confess that I am skeptical in regard to the inference to be drawn from a woman not having children. In these days so many women refuse to assume the responsibilities and joys of motherhood, that it is hard to say whether the childless women are so of choice or of necessity. Assuming that the women in my tables were childless of necessity, the fact that ten out of the thirty-four had no children, and seven had only one child, certainly bears out the prevalent idea that women with hirsuties are not so prolific as those who have not hirsuties. The number of brunettes was a little more than 2½ times that of the decided blondes. This sustains the prevalent idea that the darker the skin the more prone it is to the growth of hair.

It is when we come to the consideration of the family tendency to hirsuties that we have the most important etiological factor in causation. This is shown by the fact that in fifty-five per cent. of the cases the deformity was hereditary. Of these $66\frac{3}{11}$ per cent. were on the maternal side, only about 9 per cent. were on the paternal side, while $23\frac{7}{11}$ per cent. were probably also hereditary, as the deformity occurred in the sisters of the patients. If we add to this fifty-five per cent. the nine per cent. in which the patient was said to resemble the father, there being no other evidence of heredity, we have sixty-four per cent. of the cases in which heredity may fairly be regarded as the cause of the trouble. From this we are justified in concluding that hypertrichosis in women is very largely a matter of heredity, especially on the maternal side; that it has comparatively little to do with disorders of the reproductive organs; that brunettes are more prone to it than blondes; that a woman with hirsuties is a little less apt to bear children than one who has not hirsuties; and that the most frequent age for the appearance of the trouble is between the sixteenth and thirtieth year.

The upper lip is the most frequent site for the growth of hair, it showing the growth in seventy-three per cent. of the cases. The chin is a close second, with a record of seventy-two per cent., so that we may say that the lip and the chin are affected in equal degree, except that the lip alone was affected in fourteen per cent. of the cases, while the chin alone was affected in only five per cent. of the cases. The cheeks were affected in thirty-one per cent. of the cases, but were never alone the site of the growth. The whole of the usually bearded part of the face in men was affected in these women in twenty-three per cent. of the cases. Here again we find an analogy to what obtains in men in whom it is not uncommon to see a comparatively scanty growth of hair upon the cheeks, and the heaviest growth upon the lip and chin.

As to the treatment it is easily stated, there is but one method of treatment, and that is by electrolysis. It is scarcely necessary for me to describe the operation for the destruction of superfluous hair by electrolysis. It is one of the glories of American medical science that one of our physicians, Dr. Michel of St. Louis, introduced it to the world, and another of our physicians, Dr. Hardaway of St. Louis, brought it prominently before the medical profession as the means for relieving many a distressed woman of a burden heavy to be borne. Happily both of these worthy-to-be-honored men have reaped a rich reward for their ingenuity.

The question is often asked me: "Is the operation a successful one?" I always answer without any hesitation: "Yes, undoubtedly." There is no case, however bad, that cannot be permanently cured. It is simply a question of perseverence on the part of both the patient and the operator. It must always be borne in mind that it is impossible for any one to strike the hair papilla right every time, and so there will be a certain number of hairs return. As the operator grows more skilful the number of returns will become less. It is always my custom to tell my patients, when they first come to inquire about the removal of superfluous hair, that they must expect a certain number of hairs to come back. Another thing to be borne in mind is that in young women it is impossible to say when the new hairs will cease from appearing, and it is well also to tell them this, so that they will not think that all the hair that they see coming, after a series of operations, is a return of those taken out. It is this appearance of new hairs that has given rise to the notion that the operation stimulates the growth of hair. I have never seen any evidence of this. Indeed Giovannini has shown that the electrolytic action is not confined to the immediate vicinity

of the hair papilla operated on, but goes to a certain degree beyond it. This fact tends to show that the operation is rather inclined to discourage the growth of new hairs.

The best cases to work on are those in which the hair occurs late in life and is limited to only a few coarse hairs. By careful and slow work it is quite possible to destroy nearly all the hairs at the first sitting. When we have a great many hairs to destroy and the patient is naturally impatient to get the hair off as soon as possible, it is better to work faster, even if not with as much exactness, and to go over the face again and again until all are destroyed. Another question that is often asked is: Will the operation scar the face? To this may be answered that in the vast majority of cases, if the work is done carefully, no perceptible scars will be left. Almost all skins will show some small punctate scars left by previous operations if the skin is put on the stretch in a strong light. This is practically *not* scarring, as the little marks cannot be seen under ordinary conditions. There are some skins that bear the operation so well that even these small scars are not to be seen. On the other hand there are some skins that will scar, do what you will, and it is impossible to tell beforehand which sort of a skin you have to deal with. In almost all cases the upper lip will scar more readily than any other part of the face. If too strong currents are used, and these are allowed to work for too long a time; or if the attempt is made to enter a follicle for the second time at the same sitting; or if the sittings are had at too short intervals; or the hairs are taken out in too close proximity to one another; scarring may be expected. Only in one of my own cases have I made scars that were at all perceptible, and that was in the soft, fine skin of a Jewess, whose skin would scar, whatever I did. I have seen several women who have been operated on by others, in whom the scarring was disfiguring. But as a rule, this result is due to bad technic, and is not a reproach to the operation.

There is nothing so difficult for a man in my line of work as to follow up his cases, and to write at the end of his case-history, the final result of his work. As showing what results may be expected to follow the operation, let me briefly give you some notes from my case-book:

CASE I.—A Jewess from whom I removed nearly 8000 hairs in five months. After six weeks, when most of the hairs that were to come back had probably put in an appearance, she wrote me that she had pulled 1700 hairs. When I stopped work on her the face was by no means clear, but she was used up by her frequent journeyings to and from the city.

CASE II.—A woman of forty-four years, from whom I removed 2300 hairs. She comes to me about once a year to have a few straggling new ones removed, the tendency to hair-growth not having ceased.

CASE III.—A young woman of twenty years, from whose face I removed 6500 hairs in a long series of sittings during some four years. After a pause of five months I took out 580 hairs in another series of sittings. This left her face free of all hairs of any size. I have seen her from time to time during the five years that have elapsed since I last worked on her, and though she has not pulled a hair nor done anything to her face, no one would dream that she ever had had the heavy growth she once had, nor notice that she was the subject of hirsuties.

CASE IV.—A young woman, from the right side of whose face I removed 4800 hairs, a colleague taking about the same number from the other side. Six months after the last sitting I met her and she expressed herself as delighted with the result of the operation. Her face looked perfectly free of hair.

CASE V.—A young woman, from whose face I removed 262 hairs. Three months after I removed 32 hairs, and three months after that I took out only 9.

CASE VI.—This is the worst case that I have ever had. The patient is a young woman. She came to me in 1892. I removed, in a series of twenty-eight sittings, 2285 hairs, hardly making an impression on the growth. She went to her home for six weeks and then returned, when I took out in nine sittings 1195 hairs. After another four months 2200 hairs were removed in twenty-five sittings. Again an interval of four months, and a removal of 2745 hairs in thirty-two sittings. After an interval of five months she came again and had 995 hairs removed in ten sittings. And so on, until up to April of 1895 I had removed 11,360 hairs. Now there was a pause of six months, and another series of sittings in which some 1545 hairs were removed. During this last six months she is able to mix in company without any remarks being made, and when the last series was ended her face was in fine condition. It looks as if in one or two more series of sittings we will have the growth under easy control.

These cases will be enough to illustrate the difficulties of the work, and to show the satisfactory results arising from it.

In closing this part of my paper, I would say again that I have perfect faith in the operation, that it is a sure cure, although there are certain difficulties to contend with in attaining a cure, and that, though the operation is devoid of that brilliancy that throws a glow over the major surgical operations, it is one of the greatest gifts

of our art to that much suffering creature, woman.

TOO LITTLE HAIR.

I shall endeavor to be as brief as my subject. I shall give you no statistics, but simply state to you some things that I believe to be true. At this time I shall speak only of what is known as premature alopecia, or falling of the hair before the forty-fifth year. It must be confessed that this is a purely arbitrary division, but it is convenient. I shall say nothing of senile alopecia, for which we can do nothing; nor of alopecia areata—that is a disease of quite different nature. Nor must you take what I say in regard to treatment as applying to the reproduction of hair on a perfectly bald and atrophic piece of scalp, even though on the head of a young man. When a man with such a scalp asks us to make his hair grow, he asks too much. We cannot do anything for him. It is only of the more or less gradual, but persistent, loss of hair, that is so often seen in people who have not yet attained to middle life, that it is my intention to speak.

People lose their hair, either on account of some disease of the scalp, or on account of hereditary influences, or on account of some form of nervous or physical derangement, that interferes with its proper nutrition.

By far the most common cause of loss of hair is some disease of the scalp; and the disease of the scalp that most often causes baldness is seborrhea. This may be of either the dry or oily form. You may, if you please, call it by the name of seborrheal dermatitis or seborrheal eczema; it will make no difference with my statement or the effect of the disease. Now, when you have a well-marked seborrhea added to an equally well-marked tendency to the early loss of hair, you have a combination that is very dangerous to the hair. It is true that my highly valued friend, Dr. G. T. Elliot, believes that all, or nearly all, the cases supposed to be due to heredity are really due to a seborrhea, that caused the hair to fall in the father, as well as in the son. I cannot go as far as that, but do believe that hereditary tendencies show themselves just as much in the loss of hair at an early age as they do in so many other ills that afflict us. We have all known of families in which the hair has fallen at an early age from the heads of most of its male members, and this without any apparent disease of the scalp. A very frequent manifestation of hereditary loss of hair is seen in the receding forehead, that is a well-marked family trait. On the one hand, we see cases of seborrhea of the scalp existing for years, without alopecia, in a patient who comes of a family in which baldness is not common. On the other hand, we see cases of alopecia at a very early age, and we find a seborrhea of perhaps no great amount on the scalp. The disease of the scalp does not appear bad enough to cause the hair to fall, and inquiry brings out the fact that the patient's ancestors, with a good deal of uniformity, were bald at an early age.

Women become bald with much less frequency than men. In a recent study of my cases, I found that those women who became bald gave a history of baldness, or loss of hair in other female members of the family. If further study substantiates this, it will be another witness to hereditary influence in the production of baldness. It has been noted that women are troubled with loss of hair more often than men, but that in them the hair usually returns. So true is this that, when a woman comes to me for falling hair, unless she is growing old and shows atrophic patches of the scalp, I always feel justified in assuring her that she will not become bald. When it is a man who comes, no matter how young he may be, I never feel so assured that his hair will cease from falling or grow in again.

In women we often find anemia, chlorosis, neurasthenia, or some other form of nervous or physical debility at the bottom of the fall of the hair. We can note that the hair grows more abundant, or falls out more rapidly, with the rise and fall of the tide of nutrition in them. These conditions are not so often seen in men, but when they do occur they are just as capable of producing loss of hair.

And now, having thus briefly stated what I believe to be the underlying causes of the fall of the hair, let me state as briefly what I believe are the methods of treatment.

If there is any scaling or crusting on the scalp showing the presence of a pityriasis or seborrhea, our first duty is to address our remedies to its cure. Do not make the mistake of prescribing cantharides at once because there is falling of the hair. To some physicians, falling of the hair always suggests cantharides, just as to other physicians any skin trouble suggests arsenic. If there is much crusting, it is well to soak the scalp over night in sweet oil, with two per cent. of salicylic acid, and to wash the hair and scalp in the following morning. Then in these cases, or without the preliminary soaking in other cases, apply the chosen remedial agent. There are many who prefer resorcin, three to five per cent. in alcohol and water. I have tried this, both on

myself and my patients, and do not like it. It is, in my opinion, only fitted for those cases in which there is an oily seborrhea present. In the other forms it is apt to prove too drying to the scalp, and to increase the itching. If one tries to use a slightly oily fluid preparation of this or other drug, it is not much better. In my experience, though fluid preparations are easier to apply, they are not as much under control as pomades, and are prone to make the hair stringy and generally disagreeable.

After making trial of a great many different drugs and combinations in the treatment of the scalp, I have settled down to two formulas, namely: Sulphur cream, and Bronson's ointment. These give me such satisfaction, that I employ the one or the other in the great majority of my cases of alopecia pityrodes. My preference is for the sulphur cream. This is composed of

℞ Ceræ albæ . . . . ʒ vii
Ol. petrolate . . . . ʒ v
Aquæ rosæ . . . . ʒ ij ss
Sodæ biborat. . . . . gr. xxxvi
Sulphur . . . . . ʒ vii
Mix.

This I use whenever I can. As after a time there is a slight odor of sulphur about the head of one using this preparation, it is not well to prescribe it for physicians, or teachers, or those following any pursuit in which others are liable to detect such an odor. In such cases, and in those in which sulphur does not agree, Bronson's ointment is an elegant and efficient substitute. It is composed as follows:

℞ Hydrarg. ammon. . . . . ℈ i–ii
Hydrarg. chlor. mitis . . . ℈ ii–iv
Vaselin . . . . . ʒ i
Mix.

It is frequently said that ointments are objectionable and that patients will not use them because they make the hair so greasy. That is quite true if one uses a thick ointment and uses it too freely. But if one of the ointments here given is used and the patient be instructed to dip the end of the finger lightly into the ointment, and then to rub the small particle of ointment thus taken, thoroughly into the scalp and not to smear it on the hair, there will be no complaint. It is always best to have the ointment put on by a second person, but if this is impracticable, then the patient must be told to lay the hair in a part and to rub the ointment into the part, and so go over the scalp. Of course this takes time but it need not be done every day. After the ointment is applied, the hair is to be brushed to spread the ointment still more. The application is to be repeated once a day; every other day; or only once or twice a week, according to the nature of the case. It is remarkable how much more comfortable the scalp feels after the use of one of these ointments. Persistently used the seborrhea will be cured in most cases. It must be borne in mind that it will probably relapse, and the patient should be so told, and instructed to keep by him the ointment so that he may attack the disease as soon it appears.

The other diseases of the scalp that tend to produce baldness are so few that I shall not speak of them now.

Apart from the treatment of the disease of the scalp that may be present, I believe that there is but one other remedy worthy to be spoken of, and that is massage. It is absurd to use so-called "hair tonics," which, in most instances, are but more or less strong solutions of cantharides. If we use this irritant strong enough to cause anything but the most fugitive effect on the scalp, we are apt to set up inflammation. And if we use weak solutions and produce only a slight and fugitive irritation, what good is it? Vaunted hair tonics make their reputations very largely in those cases of transient fall of the hair after fevers, and in women, in whom we have said that the hair is apt to fall out and to grow again. Most of these cases in time would regain the hair without any so-called "tonic." They do a certain amount of good by keeping the scalp clean, and it is probable that the rubbing of them into the scalp acts as massage does, and is an accidental good result from their use. In cases in which the hair is really falling out in a vicious way, and in most cases of premature baldness in men they are, in my judgment and experience, of little value.

Massage, on the other hand, is the model method for increasing the nutrition of the hair. It does this by increasing the flow of blood, not only in the superficial vessels but also in the deep ones. We know that the hair papillæ receive their blood-supply from the deep plexus of blood-vessels that give off little arterial twigs to them. If now we increase the amount of blood flowing through the deep vessels, we also encourage the blood-supply to the papillæ, and so stimulate the growth of hair. We also accomplish another important thing, which is the loosening of the scalp. In men who are growing bald you will find that the scalp becomes progressively more and more drawn down upon the underlying bones. An atrophy of the skin is in progress. Now the application of all the local stimulants in the world

will not cause the scalp to loosen. But massage will, and this very thing will greatly aid us in our endeavor to get the hair to grow. It may not cause new hair to grow, and it may not permanently stop the progress of the atrophy, but it will at least stay its onward course and in so much delay the appearance of baldness. Believing that this reasoning is right I have long ago adopted massage as the essential part of the treatment of all cases of loss of hair that are not evidently and without doubt due to some passing and readily curable disease of the scalp. In my own practice I make use of a skilled operator when the patient can afford to employ her. Otherwise I direct him to pinch up and roll his scalp between the fingers of his two hands Happily theory and practice run together in this matter, and I have had the satisfaction of seeing a number of cases greatly improved by the use of massage.

Prophylaxis is what we should preach to all our patients, and especially to the parents. Those who come of weak-haired families should see to it that every disease of the scalp is promptly cared for; they should avoid using water on the hair as much as possible, contenting themselves with a shampoo once in three or four weeks; they should brush the hair systematically every morning and evening with a brush with long and not too stiff bristles; and they should rub into the scalp, from time to time, a little oil or fat. In this way they will stand the best chance of keeping their hair, in spite of any bad family history they may have. As the general health of the patient has an influence on the condition of the hair, we should try and get our patients into the best possible physical condition.

It is not necessary to speak particularly about the fall of hair after fevers or other illnesses. If the scalp is kept in good condition, the hair will in most cases be reproduced. I never advise that the hair should be cut from the head of a woman, or the scalp shaved in either sex. I do not believe that either does any good, and to a woman it is certainly a very serious matter to cut off the hair. Massage will do all that anything will do for these cases, together with the treatment of any disease of the scalp that may be present.

Medical Journals and a Chromo.—Evidences of degeneracy are beginning to appear even among medical journals. The most recent and mortifying example is presented in the advertisement of a semi-monthly journal, which offers a hundred dollar bicycle, of any make and style, *free* to the person sending before July 1, 1896, the largest number of subscriptions at $2.00 a year.

CLINICAL MEMORANDA.

GLIOMA OF THE LEFT CENTRUM OVALE, MONOPLEGIA, HEMIPLEGIA, WORD-BLINDNESS, ALEXIA, AGRAPHIA, PARTIAL APRAXIA AND COLOR-BLINDNESS; OPERATION, IMPROVEMENT.

By J. T. ESKRIDGE, M.D.,
of Denver, Col.;
Neurologist to the Arapahoe County and St. Luke's Hospitals,
and
CLAYTON PARKHILL, M.D.,
of Denver, Col.;
Professor of the Principles and Practice of Surgery in the Medical Department of the University of Colorado.

W. D. M., aged thirty-eight, born in Ohio, practising physician since 1882, married, living in Colorado at an altitude of about five thousand feet five years, was referred to me by Dr. Parkhill. He complained of speech disturbance and paralysis of the right leg and arm.

Father died from rheumatism, at fifty-seven years; mother is in good health. Has three brothers and four sisters, all well and strong. No consumption, mental nor nervous diseases in any of his relatives.

He has enjoyed excellent health. Has never had rheumatism, and denies any venereal disease. His habits have been excellent. As a young man he worked very hard. He has a magnificent physique, is bright and intelligent, and is said to be a good classical scholar. During the summer of 1892 he suffered from a severe attack of indigestion, which lasted six weeks and at this time he was compelled to give up work. His health was soon almost as good as before his sickness, except that he was inclined to be constipated and had to be more careful of his diet.

He dates the beginning of his present trouble from August, 1894, but his friends say that during May, June, and July of that year he was forgetful of small affairs and frequently was unusually drowsy. At times during the day, he found it almost impossible to keep awake. He worked very hard during the summer of 1894, and at one time for a period of two weeks, he obtained very little sleep. In August, 1894, he noticed that his right hand was getting weak, but he could still write nearly as well as formerly, except that he wrote more slowly and occasionally omitted words. The right hand was first affected, next the forearm and finally the upper arm and shoulder. By the middle of September, the entire right arm was completely paralyzed. Just when he ceased to be able to write he does not remember. The tendency to sleep during the day became troublesome in August, so that he found it impossible to keep awake while at work in his office. Sometimes he slept heavily all night, on other occasions he found it almost impossible to get any sleep on account of restlessness. He suffered from no headache nor gastric disorder. Early in September he found difficulty in talking as he would get his words mixed. By the second week of that month almost every sentence that he tried to utter had one, and sometimes several, words omitted.

His speech, however, was understood by others. He recognized his mistakes and would laugh at his inability to say what he wanted to say. He kept at his work, but had to dictate his prescriptions until October 20th. The next day he found that he was totally unable to say what he desired to have written, and on trying to read he was unable to do it. He could pick out a word or two in a sentence and understand them. He had no difficulty in comprehending what others said to him.

October 23d, he started for Galveston, Tex. His right arm was completely paralyzed. He could not say anything except "yes" and "no" and these were often used wrongly. His only symptoms when he left Denver for Texas were paralysis of the right arm and speech disturbance. During the journey there, extending over a period of three days, his right leg became very weak, so that he was unable to dorsally flex the right foot to its normal extent, and soon was forced to drag the right foot in walking. The whole limb felt cold and "dead." During November and December, his leg was worse, but arm and speech remained about the same. Some time in November he began to have great difficulty in dressing himself, and would at times put his clothes on with the inner side outward, reverse his shoes, and get his vest on over his coat. In December, 1894, the right shoulder, arm, and hand became hyperalgesic to such an extent that the least rough usage of these parts caused intense suffering. This condition remained about three months, then these parts felt cold and numb. During his stay in Texas he suffered for two weeks from severe headache. With this exception there had been no headache before he consulted me. The difficulty in dressing himself became so marked that his wife joined him January 10, 1895. Soon after that time he began gradually to improve, and a month or so later he could raise his right hand to his head. walk fairly well and utter a few simple words. In March, 1895, he walked eight miles one day. During that month he traveled alone from Galveston to Iowa, where he remained until May 1, 1895, and slowly improved. On his return to Colorado he could utter the principal words of a sentence, and at times could make himself understood. He employed and understood gestures. He could not use his right hand at all, but he could raise this hand to his head. His right leg had almost completely recovered. The only trouble observed was a tendency to let the front of the foot fall in walking. He learned to ride a bicycle and rode long distances without much difficulty. During June his speech became much worse and he had to give up riding the bicycle on account of the weakness of the right leg. From December, 1894, to June, 1895, he felt dazed.

At present he feels quite well, but has little power of endurance. Is unable to form sentences or to write. He understands everything said to him and can count money. His memory is good. He can sing all the tunes that he knows, and can repeat, in a fair manner, short verses of poetry or a few lines of prose learned when he was a child. There is no vomiting, dizziness, headaches, or convulsions. He complains of no disturbance of the special senses, but thinks his taste was blunted last winter. His physical condition in regard to muscular development and the presence of fat seems excellent, although he is ten pounds lighter than he was before the beginning of his present trouble. He has a dazed and confused feeling when he gets tired. He sleeps well and does not get drowsy during the day as he did a year ago. When he is in the recumbent posture he talks better than he does when he is sitting or standing.

July 12, 1895. Gait is slow and halting. He drags the right foot and the toe of the shoe is greatly worn as the result. There is no distinct ataxia, besides a little jerky and uneven movements of the muscles on voluntary motion, in the leg, arm, or trunk muscles. If there is any ataxia of the right arm it cannot be distinguished, as its muscles are so nearly paralyzed.

Muscular Power.—Right leg, plantar flexion fairly strong; dorsal flexion very weak, and he is unable to bring the foot at right angles with the tibia. There is a slight contracture of the plantar flexors. Knee and hip muscles are weaker than those of the left leg, but still are fairly strong. Left leg muscles normal. Arms: Dyn. R. 18; L. 166. There are flexor contractures of all the fingers of the right hand, upon the hand, of the hand upon the forearm, of the latter upon the upper arm, with quite firm adductor contractures of the upper arm against the chest. The contractures of all the muscles can be overcome by force without giving rise to pain, except those that adduct the arm. The tongue deviates slightly to the right in extreme protrusion, but not if only moderately protruded. The right lower side of the face is paretic, so that voluntary motion is lessened, but as seen in smiling, emotional motion is not perceptibly affected.

The muscles of the thenar eminence and the interossei muscle of the right hand are the only ones that present a wasted appearance. These are considerably atrophied, but respond about normally to the faradic current.

Reflexes.—Knee-jerks; R., enormously exaggerated; L., considerably increased over the normal. Both influenced by reinforcing. Ankle-clonus: R., present; L., absent. Tendo-Achillis: R., exaggerated, with marked clonus; L., increased. Plantar absent. Cremaster: R., absent; L., well marked. Abdominal reflexes absent. Extensors of forearms: R., greatly exaggerated; L., about normal. Biceps: R., exaggerated; L., slightly increased. Triceps about the same as the biceps. Deltoid: R., well marked; L., absent. Pectoralis major: R., pronounced; L., absent. Masseter absent. Pharyngeal and iris reflexes present. Sensory phenomena: Right side. Tactile sense is present throughout this side, except on the distal portions of the fingers, where a camel-hair pencil cannot be perceived, even when it is in motion. Throughout this side, but more marked in the distal portions of the leg and arm the sense of touch is blunted. Localization is perverted and lessened everywhere, and almost completely lost on neck, trunk, arm, and leg. When the right hand and foot are touched he not infrequently refers the impression to the corresponding part on the left side. Temperature sense is lessened in face and nearly absent in parts below the face. Pain sense acute throughout the entire side. Posture sense apparently present, although

his speech difficulty makes it impossible to be absolutely certain in regard to this point. Muscular sense absent. Pressure sense uncertain. Joint sense seems to be present. All general sensory phenomena normal in left side. Smell and taste present and equal. Hearing; watch, R., 2/3; L., 2/3; tuning fork test not reliable, and he gets excited and confused in trying to understand what I want, and in endeavoring to make me understand his impressions.

Eyes.—Vision: R., 20/30; L., 20/30; fields normal; all the external ocular muscles act well; pupils equal in size and respond readily to light and accommodation. Fundi normal.

Mental Condition.—Early in the examination his mind appeared quite clear, but as soon as he became fatigued he at once showed evidence of mental confusion. Further examination was deferred until he was rested.

Speech.—Most of the objects that he sees he recognizes at once, but those less familiar to him seem to confuse him. When objects are presented to him by hearing, taste, or smell, he recognizes the familiar ones as readily as when he sees them. On the right side tactile sense is too dull to enable him to recognize objects by feeling them. On the left side certain qualities are readily appreciated by tactile sense.

He appears to know the use of all familiar objects, so far as he is tested. He is unable to recall the spoken names of objects presented to him through any of the senses, but for most familiar objects he recognizes the name of each when it is repeated. Not infrequently, however, especially if he is a little fatigued, he becomes confused about the names of objects that are very familiar. There is a condition of verbal amnesia for the names of familiar objects and probably apraxia for those less familiar. When he is blindfolded and called by his wife, he smiles and says, "That's all right, but I can't say it, no." He means that he knows who is calling him but he cannot recall her name.

He understands sounds other than speech and speech and music. He is very fond of music and is said to have been quite proficient in it. He has no difficulty in singing a familiar tune if his wife will lead, but he cannot be gotten to start and sing a tune unassisted. He promptly calls to mind the objects named and points them out. He has no difficulty in recognizing and pronouncing a word spelled aloud, and he can call up mentally the sound of a note, figure, letter, or word.

He is unable to recognize a note, rarely a letter, but occasionally he recognizes and even calls the names of some figures. He is totally unable to understand most printed and written words. He recognizes his own name, points to himself and says, "that all right." He is unable to read printing, writing, or music, either aloud or inaudibly.

In a few instances only can he recall an object, the name of which is seen. This power is retained for a few of the most familiar objects, the names of which are short, such as dog, cat, rat, book, longer names of equally familiar objects give him no idea of the object, *e.g.*, matchbox, penknife, handkerchief. Less familiar objects with short names are not recalled by seeing their names, *e.g.*, parrot, grouse, quail.

On testing his power to write voluntarily, his name fairly well written with his left hand, is the only result. After he writes his name at the first attempt, I tell him to write something else. He hesitates a while, and again writes his name. This is repeated several times. He cannot write at dictation. He copies fairly well with his left hand, the right being completely paralyzed, but the copy is made mechanically, writing appearing as script and printing as printing in the copy. Each letter received the degree of shading found in the original. He cannot write the names of any objects presented to him by any of the special senses, and does not know what he has written when he copies, except it be his own name. He can write his name voluntarily, and at dictation, and can read it when written by himself, by another person or when printed.

Generally he does not seem to be able to recognize a letter or figure when his left index finger or hand is made to trace it, but sometimes he would say, "all right," meaning he knew, but on questioning him if he were sure, he would wave his hand in front of his face, meaning that he was confused or uncertain.

In testing his power to call up mentally the appearance of an object, a figure, note, letter, or word, it is impossible to determine accurately the extent of the defect, as he sometimes says "no" when he means "yes," and *vice versa*. He does not seem to have any difficulty in mentally calling up the appearance of objects, but for those of figures, notes, letters, and words there is a grave defect.

Voluntary speech is much impaired. If he is asked to say something he will simply say "It's all right," then smile at his failure, or look vexed and say "Oh pshaw!" At times he endeavors to make his wants known by speech. He will utter one or two of the principal words of a sentence, make a few gestures and look anxiously for some one to complete the sentence for him. If the wrong word is supplied he immediately rejects it, but when the right one is suggested he accepts it with an approving smile. The defect in voluntary speech is due to verbal amnesia.

He can repeat long and difficult sentences after another if one word is uttered and he is allowed to repeat it before the second one is spoken. If several words of a sentence are uttered he will say one or two of the principal words, but will leave out the articles, pronouns and adjectives, etc. The defect in repeating words after another appears to be due to his inability to remember more than one or two words at a time. If he is asked to repeat a word over several times and told to try and remember it, five minutes later it is found that he has entirely forgotten it.

He recognizes many, but probably not all, of his mistakes in speaking or writing, but is powerless to correct them. If his mistakes in speech are corrected for him, he recognizes and appreciates it. If his mistakes in writing are corrected for him, he does not recognize it, but accepts it by saying "Don't," or "Don't know," or "All right."

The patient has no difficulty propositionizing or thinking in speech. There is no special difficulty with one

part of speech more than another. His memory for nouns or the principal words of a sentence is better than for the less important words. He understands and employs gesture expression in speech.

He cannot read figures or calculate, neither can he count in numbers. He recognizes money and succeeds in making change. He cannot play a game of cards.

All the internal organs, except the brain, were apparently normal.

After completing the examination I concluded that the doctor was suffering from tumor of the brain, which was large and rather diffuse in character, and that it was situated in the left cerebrum, subcortical, at least in its early stage, to the angular and Rolandic regions. I advised as the only hope, an early operation for its removal, but requested him to go to the St. Luke's Hospital and let me study his case daily for a while before submitting to an operation. He accepted my diagnosis without hesitation, and gave me to understand, aided by his wife in communicating his wishes to me. that he would follow my advice to the letter.

His wife further stated that her husband had been convinced for some time that he was suffering from tumor of the brain and had desired to have it removed, but physicians and relatives had opposed such a procedure.

He entered the St. Luke's Hospital, July 13, 1895.

Careful temperature observation of the heat of the mouth and the two axillæ were made several times each day, together with a record of the pulse and respiration. I desire, in this connection, to acknowledge my indebtedness to the intelligent coöperation of the pupil nurses in the training school of the Hospital, for the careful and efficient manner in which they made observations for me. I personally made several comparative surface temperature observations of the head on several different occasions, and from time to time verified the accuracy of the axillary and mouth temperatures taken by the nurses. In all the temperature observations the Fahrenheit scale was used. July 13, 7 P.M. axillary temperature, R., 98.2°; L., 98.2°; P., 78; R., 22. Head: temp., temporal; R., 94.8°; L., 95.3°.

July 14, 7 A.M. the axillary temperature was 97.3° and practically the same on each side; pulse and respiration about the same. It was observed that he got his shoes changed in putting them on, and he did not seem to be able to correct his mistake without the assistance of the nurse. At noon, temperature, axillary: R., 97.2°; L., 97.3°; mouth, 97.8°; P., 68; R., 20. Head temp.: Temporal: R., 96.2°; L., 96.6°. Mid-Rolandic: R., 96.1°; L., 96.5°. Parietal eminence: R., 96°; L., 96.2°. During the remainder of the day the record was practically the same.

July 16, 6.30 A.M.: temp. mouth: 97.2°; axillary: R., 96.6°; L., 96.8°. Pulse and respiration unchanged. It was observed on that day that the fields in the right lower quadrant of each eye were a little contracted.

During the next four days temperature was not above normal.

July 18, the following notes were made. "All the movements of the right foot and leg are fairly strong, but they are slow and awkward, especially at the ankle. Right shoulder movements are strong, but these also are slow and awkward. He cannot rotate the right forearm, move the thumb or any one finger of this side separately. Thumb remains almost motionless, even when he attempts to move it in association with the fingers of the hand, He can slightly flex the fingers of the right hand, when all the fingers are allowed to move at the same time, but it requires an extraordinary effort on his part to do this, and it is attended by movements of the right elbow and shoulder, and flexor contraction of the fingers of the left hand. Right foot and hand are cool and dark from venous stasis.

The Rolandic region, the greater portion of the parietal lobe, especially the inferior parietal lobe and the angular gyrus of the left side, all seemed to be involved by the lesion. It was thought that a trephine opening through the skull just below the parietal eminence would expose the center of the morbid process, which was thought to be a tumor. The operation and surgical aspect of the case will be found described by Dr. Parkhill.

After I had satisfied myself that the patient was suffering from some organic brain lesion and not from a mere hysterical or functional condition, the further differential diagnosis seemed to lie between a vascular lesion and abscess or tumor.

The absence in the history of the case of all evidence of apoplectic or apoplectiform symptoms inclined me to regard the case of non-vascular origin. The gradual onset of the symptoms beginning in the right hand, later affecting the forearm, upper arm, and shoulder, and finally involving the leg of the same side, is contrary to what we find to result from vascular lesions. A small area of softening may take place from the occlusion of small vessels and later by the occlusion of other vessels, the area of softening may extend and involve adjacent centers to those first affected, but in such cases there is a history of slight apoplectic attacks.

There was no detectable cause for abscess of the brain. Besides when a cerebral abscess becomes extensive enough to produce hemiplegia, the brain function is so interfered with that life, as a rule, is prolonged only for a few weeks at most, and generally only for a few days. Decided improvement in such cases rarely, if ever, takes place, and if it should occur, it would not be maintained over a period of months.

I was forced to the conclusion that I had a tumor to deal with. Could the symptoms be accounted for by the presence of a tumor ?

A tumor in the centrum ovale, in which intracranial pressure is not much increased, may be unattended by optic neuritis, headache, nausea, vomiting, vertigo, and convulsions, and its presence may be suspected only when fibers of the corona radiata are involved, the connection of which is with more or less definitely known centers of the cerebral cortex. The gradual development of the symptoms, beginning in the distal portion of a limb and extending toward the body is a common occurrence in intracranial tumors, situated in the cortex or immediately below it. Rapid development of symptoms, after the dis-

ease has existed for some time, followed by periods of weeks or months during which the disease does not advance, but may retrograde considerably, occurs in some vascular growths, especially of the sarcomatous and gliomatous varieties. There did not seem to be any symptoms that could not be accounted for by the presence of a growth in the centrum ovale. The history of the case indicated that the growth was a glioma or sarcoma.

THE SURGICAL ASPECT OF THE CASE.

By Dr. PARKHILL.

On July 19, 1895, preparation was begun for the surgical side of the above case. The scalp was shaved, measured, and the markings made permanent by nitrate of silver solution. The scalp was then scrubbed with soap and water, with ether, and finally with a solution of mercuric chlorid. Dressings wrung out of these mercurial solutions were then applied, to be left until the time of operation. He was given a purgative of epsom salt on the evening of the 19th.

The operation was begun at 11.30 on the morning of July 20th. The markings of the scalp were transferred to the bone by the Parkhill skull marker. The scalp was then raised and a button of bone was removed just posterior to the arm center in the left Rolandic region. This opening was enlarged with rongeurs, until it had a diameter of about an inch and a half. The bone proved to be quite vascular and hard and had about the normal thickness. The dura was then opened by a crucial incision. The underlying membranes seemed normal. There was no pulsation and the brain was much more firm and resistent to the touch than normal. The exposed surface was of a dirty, yellowish color. It then became apparent that the tumor had a greater area than the bony opening, so this was enlarged until it had a diameter of about two and a half inches, The membranes were also opened to a corresponding degree. The tumor was cut away piece-meal, with a sharp Volkman spoon. It was quite firm and tough. The yellowish discoloration which was perceptible on the surface was found to prevade the entire mass. Its limits were made out only by lessened resistence to the instrument and a change to normal color. Some embarrassment was encountered from hemorrhage, but not more than is usual in the removal of such growths and it was rapidly controlled by plugging and slight pressure, by means of sterilized gauze. This growth approximated a circle, having a diameter of about two inches and extended to a depth of about three-fourths of an inch.

The membranes were reunited with catgut, except at the most dependent point through which a small rubber drainage-tube was inserted, and this was brought out through the middle of the scalp flap. The scalp was sutured with silkworm-gut, the usual dressings applied, and the patient returned to his bed, the operation having occupied something less than an hour.

The patient exhibited considerable shock for the first few hours, his axillary temperature dropping as low as 96.8°. It had risen, however, to 98.3° at 6 P.M. He was stimulated by alcoholics and heart tonics for twenty-four hours. His recovery, from a surgical standpoint, was entirely uneventful. His temperature fourteen hours after the operation reached 100.6°, but dropped to 99.6° at the end of eighteen hours, which was never exceeded afterward.

On March 22, 1896, seven months after the patient had left the hospital following the removal of the tumor, I lifted the scalp over this area, dissected it away from the dura, and inserted a piece of gold foil the size and shape of the bony opening. This was dressed on the sixth day and found perfectly sound, and the patient was sent home.

SUBSEQUENT HISTORY OF THE CASE FROM THE STANDPOINT OF THE NEUROLOGISTS, WITH REMARKS.

By Dr. ESKRIDGE.

Angust 7, 1895, eighteen days after the operation, I first examined the patient. His condition then was nearly the same as it had been before the operation, except that the right leg, especially at the distal portion, was weaker. He could, however, read a few words and point out most objects, the names of which were spoken. The optic disks and ocular fundi were normal in appearance. The fields were well preserved, except a slight narrowing of the right lower quadrant of each eye. Central vision was good.

October 17th he was again examined. The paralysis, especially of the face and leg, were decidedly less than before the operation. He was able to count money and to make change. He did not seem to be able to recognize colors. His speech was a little better.

October 28th, at 3 A.M. he had a general convulsion. The night before he had eaten heartily of pumpkin pie and had been constipated for three days. The right hand began to jerk, he screamed and a general convulsion, involving both sides of the body occurred. The left side was less affected than the right. During the convulsion and for an hour or two after it, the soft parts were protruding through the opening in the skull and were pulsating. After his bowels had been throughly opened by an enema, he regained consciousness, the brain receded and all visible pulsation ceased.

November 19th, the doctor drove from Longmont to Denver, a distance of thirty-four miles, without being fatigued. He was much improved physically and mentally appeared clearer. His wife stated that he had been trying for some weeks to read the papers, and was frequently able to tell some things that he had read. On my testing him I found that he did not know a letter of the alphabet. While riding along the road he repeatedly pointed out objects and spoke their names, *e.g.*, "Hello, a Jersey calf." He was still able to pronounce any word that was spelled aloud for him. He was beginning to re gain some in voluntary speech, and could recall some objects, the names of which were seen. He could recall all objects, the pictures of which were seen, and often name them. He could read and pronounce the word "box" and pick out a box from several objects on the desk, yet he could not recognize a single letter employed in spelling the word. He could count money readily, but could not count by numbers. It was observed that words

called up ideas, *e.g.*, "river" he called "water"; "Paris," "France"; "Council Bluffs," "Iowa." Of late he has been able to play games, both with checkers and cards.

The muscular rigidity was very much less; the knee-jerks were nearly normal; ankle-clonus was absent; deep reflexes of right arm still very much exaggerated; he could pronate and supinate the right forearm, and raise the arm without assistance above the head. The next day he came into my office alone; I asked him where his wife was. He promptly replied "trading," meaning shopping. Dr. Charles F. Andrew, of Longmont, Col., kindly made observations from time to time for me. He found that the patient could not sing a tune unless it was started for him. In trying to whistle a tune he would get the wrong one, but would recognize his mistake. On December 20th; he still had great difficulty in recognizing colors.

January 3, 1896, Dr. Andrew found the fields of vision normal, and the central vision good. His color sense was much impaired. He could calculate and count into the hundreds. He read a number of words, but recognized only one letter of the alphabet, "a". He recognized six out of nine numbers written. During the first week of January, while his stomach was out of order, he had his second convulsion, similar in every respect to the first.

March 8, 1896, he was examined again. Muscular power in the right hand had improved a great deal. Dyn. R., 50; L., 170. Contractures and deep reflexes were lessened. He walked fairly well and was able to harness and unharness his horse. He could drive long distances without becoming fatigued. Localization sense was greatly perverted, or nearly absent throughout the right side, except in the face. Tactile sense was present, but lessened. Temperature sense was absent throughout the right side, except in the face. Cold substances were called hot, and hot substances (temperature of 120°) were scarcely felt. Pressure sense greatly lessened; joint sense present; pain sense was lessened, but not abolished. Posture and muscular senses were absent in right arm. Hearing, smell, and taste showed no change. He had improved some in speech, especially in repeating longer sentences than he had been able to do before the operation. Voluntary speech was a little better, but he was still completely letter blind, word blind, for all words except very familiar ones. He was unable to write voluntarily, and had made very little progress in learning to read.

On March 11th, he had his third convulsion.

On consultation with Dr. Parkhill, it was decided to raise the scalp and insert gold foil between it and the dura, as it was feared that adhesions had formed between these and caused the convulsions. Firm adhesions were found between the scalp and dura.

As all the convulsions have begun in the right hand, and firm adhesions were found between the dura and scalp over the center for this hand, it is probable that the insertion of the gold foil will prevent the irritation which gave rise to the initial convulsive movements.

The result in this case, although a complete cure cannot take place, is encouraging toward further and earlier operations for the removal of tumors of the brain. The tumor was thought to be quite large before the operation, but it was hoped that an encapsulated sarcoma would be found, instead of an infiltrating glioma. Had the enormous size of the tumor and its infiltrating character been known before an attempt was made to remove it, it is very probable that an operation would have been discouraged. After the operation the wife was told that there was little to be hoped for, as the tumor would in all probability return. At the end of ten months improvement still continues, and there is no evidence that the growth has returned. In such cases, even if no better results can be obtained than has been achieved in this one, the outcome fully justifies an attempt to remove the growth. A person in the patient's present condition is able to enjoy life.

REPORT OF A CASE OF LANDRY'S DISEASE.

BY R. E. LEWIS, M.D.,
OF MACOMB, ILL.

ON the morning of July 20, 1894, I was called to see Mrs. G., aged fifty-three, whose occupation was household duties. Her family history was good, most of her people living until well advanced in years.

For six months previous to the present attack she had been under great mental and physical strain, which was followed by exposure by sleeping at night where a strong current of air passed over her body, and now complained of distressing paroxysmal pains shooting down both lower limbs, beginning at the exit of the sciatic nerves, and following them to their terminations. Very slight tenderness was detected by pressure where the nerves became superficial. Aside from this the patient felt comparatively well. Her temperature was 100⅖° and pulse 85. She was put to bed and ordered phenacetin and sylicylate of sodium each grs. v every three hours. She rested well that afternoon and passed a comfortable night.

On the following morning, July 21st, I found my patient entirely free from pain, in good spirits, and expressing her desire to get out of bed, which was refused, but permission was given to sit up in bed at short intervals during the day. At this time she called my attention to a slight tingling in the right leg which she described as a vibratory sensation. Her temperature was 99⅖° and pulse 78. The phenacetin and salicylate were now discontinued and gentle friction to the limb ordered.

July 22d the general condition remained the same, appetite good, and free from pain, but now she informed me that the tingling had become noticeable in the other limb, and in getting in and out of bed she found that her limbs did not support her as usual and some assistance was necessary. This was not because of pain in the members, but because they gave way beneath her and felt heavy.

July 23d I found complete loss of motion in the right leg, with only partial motion remaining in the left. The patellar reflexes were both absent but the sensation over the limbs was normal. Her temperature at this time was 101⅘°. The appetite was good and she had no pain.

On the morning of the 24th I was called early to empty the bladder, which she had been unable to accomplish.

The urine was dark, of high specific gravity, free from albumin and sugar, but giving quite a deposit of urates and phosphates. From this time until the termination of the case there was complete retention of urine and feces. The paralysis had been gradually creeping up, and now there was complete loss of motion in both lower limbs and muscles of the trunk, so that she could neither sit up nor turn herself in bed. When propped up she would soon slide down and become doubled up. Her temperature was 101°; mind clear. The 25th was marked by a rise in the temperature to 104° and numbness and tingling now appeared in the hands, the right slightly in advance of the left. The grip in each was considerably reduced. At different times during the day the lower limbs became moist with cold perspiration.

July 26th the temperature fell to 103°, where it remained during the 26th and 27th. There was gradual progression of the paralysis in the arms, with a continuation of other conditions the same.

July 27th she showed complete loss of motion below the elbows and diminished activity above, with slight disturbance of mind.

During the 28th the mind became more disturbed and she talked incoherently. Her pulse, which at no time became rapid, was now 60, and her temperature 101⅖°. Before night motion in the upper extremities was entirely suspended, completing the paralysis of the trunk and all extremities. There were several attacks of syncope during the day and following night, but death did not ensue until 9 A.M. of the 29th, about eight days from the onset of the disease.

I report this case under the head of Landry's disease with some hesitancy, for in looking over the literature upon the subject there is found quite a diversity of opinion as to what actually constitutes the disease in question. Some authors contend that it is one form of myelitis, and others that it coincides exactly with multiple neuritis, while others do not mention it at all.

It is easily separated from acute myelitis by the complete absence of sensory and trophic disturbances almost invariably present in the latter disease, no matter how sudden the onset or how rapid the progress. The disease with which it is most apt to be confounded is multiple neuritis, and certainly they have many symptoms in common which renders a diagnosis not only difficult but sometimes impossible.

It will be noticed in the above report that quite an elevation of temperature occurred at different times during the course of the disease, which most authors refuse to accept as one of the symptoms of Landry's disease, although H. C. Wood[1] states that this may occur. Its presence gives the case the appearance of multiple neuritis, but the existence of the bulbar symptoms so constantly present in acute ascending paralysis, coming on in the regular progress of the disease seems to overbalance this point, and throw the weight of evidence in favor of the latter. At best, the differentiation is made with difficulty, and cases resembling either are worthy of being reported, that our knowledge upon the subject may become more complete.

[1] "Pepper's American Text-book of Theory and Practice."

Up to the present time no specific has been offered in the treatment of these cases, and all efforts at stopping the rapid progress of the disease seem unavailing.

The etiology is somewhat obscure, but it is strongly suspected that the malady is of bacterial origin. Possibly when this is more thoroughly demonstrated we shall have a remedy put within our reach which will prove more effectual than anything which has yet been brought forward. This is sincerely to be hoped, since, with our present armamentarium, we are practically helpless.

THERAPEUTIC NOTES.

The Treatment of Diphtheria with the Antitoxin.—VIRNEISEL (*Munchener Medicinische Wochenschrift*, 1896, No. 19, p. 456) reports the results obtained at the City Hospital of Coblentz, in the treatment of diphtheria with the antitoxin, from October, 1894, to April, 1896. During this period 158 cases came under observation, of which number 8 were given no injections—3 mild cases for control purposes, 5 cases in extremis. Among the 150 cases there were 19 deaths (12.7 per cent.); 64 cases presented grave laryngeal complications, and 5 of these were almost moribund when they came under observation. Fifteen of the 64 cases requiring tracheotomy terminated fatally—23.4 per cent.—(as compared with from 56 to 64 per cent., in previous periods). Albuminuria was observed in 67 cases, of mild degree in all but 5. Other than passing skin eruptions, unpleasant secondary effects, were not observed in any case.

For Acute Coryza.

℞ Zinci phosphidi gr. vijss.
Extracti belladonnæ gr. vj.
Mix. Fiat pilulas No. xl.
S. One thrice daily, after each meal.

In case of general impairment of nutrition one grain of arsenous acid may be added to the foregoing prescription. —*Gaz. hebdom. de Méd. et de Chir.*, No. 42.

The Serotherapy of Exophthalmic Goiter.—In a case of exophthalmic goiter in a woman, thirty-two years old, GIOFFREDI (*Semaine Médicale*, 1896, No. 26, cii) observed improvement follow hypodermic injections of the blood-serum of a thyroidectomized dog presenting all of the phenomena of the cachexia strumipriva. The serum obtained with antiseptic precautions was sterilized, and had added to it .1 per cent. of cresol. In the course of forty-seven days thirty-seven injections of from .5 to 1 c. cm. each were made; and after an interval of two weeks seventeen additional injections, each of 2 c. cm., in the course of twenty days. In the course of the treatment there was almost complete cessation of the headache, the anorexia, the agitation, the trembling, diminution in the exophthalmos, improvement in the general condition, and a return of menstruation. This result, however, was but temporary, as the symptoms returned gradually upon suspension of the treatment. When the dose of the injection exceeded 1 c. cm. there occurred slight febrile reaction.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,

INTESTINAL ISOLATION.

EISELSBERG has written an interesting review (*Nederl. Tijdsch. v. Geneeskunde*, 1896, No. 8) of this distinctly modern surgical procedure. The operation aims to separate from the alimentary tract any portion of the intestine which is irritated by, or obstructs the passage of, feces. The bowel is cut through on either side of the affected portion, and the ends sutured together, *i.e.*, a "short circuit" is made about the stricture or tumor. The latter remains *in situ* and may be treated in a variety of ways. Either end or both ends may be attached to the surface of the abdomen and a fistula be established; or one end may be sutured to the other, thus making a ring; or both ends may be closed and the isolated bowel dropped back into the abdominal cavity. Eiselsberg considers a fistula necessary to give escape to the intestinal secretion. Although the three cases in which perfect closure was made prove that sometimes the amount of secretion may be so small as to give no trouble.

No less valuable is the fact that a tumor which seems inoperable may so dwindle when it is cut off from the intestinal current that a radical cure is to be hoped for by its extirpation.

Altogether the operation has been performed thirteen times, including four cases of the author. In two of these four cases a cure was obtained; in one the result was unsatisfactory, and one died.

This operation suggests the use of a segment of intestine to close a gap in another part of the intestine. Thus, if so much of the hepatic flexure be removed that the ends cannot be brought together, it would be possible to make good the continuity of the bowel by sewing into the gap a loop of small intestine. This would make necessary three lines of circular intestinal sutures. It has never been attempted in man. But it has been successfully performed in dogs.

MANUALS OF DOMESTIC MEDICINE.

IT is with considerable regret that we learn of the publication of a new "Manual of Domestic Medicine," offered by a publishing house in New York City. It is recommended as "of service to physicians, medical students, and trained nurses." Could it be kept in the hands of these, it might at least do no harm. But it is sure to have a sale among the laity, and no doubt it was primarily intended for them. Such a publication does harm to the physician by increasing the interference with his work by some member of the family, and probably by the patient himself, and does harm to the patient by suggesting temporizing and self-prescribing.

It is difficult to surmise how a physician of experience and standing can write or compile such a work. It is an entirely unscientific and unprofessional proceeding, for it presupposes that everyone to whom the book is sold is able to make a correct diagnosis. It begs the question of the science of medicine by abolishing that fundamental essential. If everyone can name his or his neighbor's disease, and if disease can be combated by rote, of course anyone can take a book, a teaspoon, and a selection of medicines, and proceed to treat himself or his neighbor. There is undoubtedly a great deal of information, which some member of every household should possess, in order to save the patient from loss until a physician can arrive. Were the book under consideration a manual merely of such information,

we would welcome it, if it contained anything new. But it is a "Manual of Medicine, Surgery, Hygiene, Dietetics, and Nursing!"

Every physician of experience has been taught in a different and a better school than one of Domestic Medicine. It is an an insult to an educated physician to offer him such a work as the present, and no medical teacher would think of putting such a compendium in the hands of his students. "Domestic Suggestions" is not the pabulum on which medical students are fed.

Who of us has not had under his care, at some time, a harassing patient, who had "studied medicine" for a few hours, and who knew more about the human frame and medical science than his physician, in spite of the latter's years of study and experience? The writer is now in attendance upon a lady who has read some book on medicine, and who gives him points regarding proper methods of treatment daily. She informs him that "the systole of her heart is all right, but the aristole is not"; again, that no physician ever gives trional "without watching the urine all the time"; again, that she has pains through "the cervix," when there is gas in her colon, varying this statement with the assertion that "the fundus is very painful." Another patient has insisted that the physician has been wrong in his treatment of him for over six months [during which time the patient has rapidly improved], because he had decided that all that was at fault was his "duodum," which he could not locate." He has obtained his smattering of dangerous quasi-medical knowledge from such a work as the one we criticize. Without knowing the shape, position, use, or function of the "duodum," he was convinced of the diseased condition of that organ. This superficial and absurd pretense of medical information would be laughable, were it not for the fact that those who possess it compel the physician to argue, explain, and teach, a process that must be repeated every day; a process that does no good, for the ignorant one who demands and hears the explanation cannot remember enough of it to apply it properly on a later occasion. Instead of profiting by it, he invariably misquotes the physician, and thereby damages him to a certain extent.

The publication of this "Manual" is useful simply for advertising the author, or for the financial return it will secure. It can subserve no good medical purpose which could not have been accomplished in some entirely professional way.

RESUME OF RECENT PROGRESS IN SURGERY.

THE TREATMENT OF FRACTURES.

THE subject of fractures has in recent years, in this country at least, been somewhat overshadowed by the advances in operative surgery. American surgeons have, however, always manifested a keen interest in the repair of fractured limbs, and many of the most important methods for the treatment of this class of cases have been devised and perfected by them.

For the treatment of fractures of the lower extremities two new methods, or, rather, modifications of old methods, have been recently proposed in Europe and have already been employed to a considerable extent in the United States. Each of these possesses features of novelty and also of practical utility. Each is worthy of more extensive trial.

The first is the method of "massage and mobilization," which has been systematized and strongly advocated for the past six years by Lucas Championière. He claims that this method is revolutionary and paradoxical, and one absolutely new and contrary to the theory and practice of surgeons. Such terms are, however, extreme for the plan is not entirely novel though it has never before been carried into execution in such a systematic and thorough manner as is advocated by this surgeon. According to this method immobilization of the limb is avoided. Massage is begun at once—the sooner the better—and employed daily until the bones have united. The seances as a rule last fifteen to thirty minutes. At first the manipulations must be gentle, and pressure should not be made directly over the ends of the fragments. In the intervals the limb is supported merely by a flannel bandage evenly, but not tightly, applied or by sand-bags alone. Splints or other immobilizing apparatus are not employed. The claims advanced for this method are: rapid disappearance of pain and swelling, prevention of and more rapid absorption of the

edema and infiltration of the soft parts and of the effusion in the joints, preservation of muscular nutrition, and the more rapid formation of a firm callus. As a consequence the fracture is followed by but little stiffness of either muscles, ligaments, or joints, and as soon as the bone is united the function of the limb is fully restored and the patient thus saved weeks or months of pain, stiffness, and disability. In certain cases, however, the originator of this plan grants that his treatment cannot be carried out in all its details. When the mobility of the fragments is so great that there is danger of a permanent deformity, or when the ends are so sharp that manipulation is apt to produce repeated traumatisms of the soft parts, or where the vitality of the skin has been endangered on account of the severity of the injury, the use of massage should be postponed for a week or two and the limb may be even confined for a few days in splints. There can be no question but that in certain cases this plan of treatment possesses advantages over the recognized treatment by complete immobilization. For example, in fractures of the radius or of the fibula the period of inability will probably be considerably shortened. It is not, however, a safe method to employ in every case of fractured leg. The risk of bony deformity is probably increased and it is very doubtful if either the patient or surgeon will be satisfied with a crooked limb even at the expense of a shorter and an easier convalescence. In many cases this method must prove a dangerous one, and it therefore cannot be recommended for routine practice.

The other method is the so-called ambulatory plan of treatment for fractures of the lower extremity, but especially of the leg. The method is not entirely novel, for at different times it has been used by surgeons in this city, though perhaps not in the systematic manner in which it is now practised in Holland, Germany, and in our own country. Plaster-of-Paris has always been largely employed in this country and has been especially popular in New York and Boston, in which cities, indeed, its use has been for many years almost universal in the treatment of fractures of the leg. The fracture-box has happily disappeared and in most of our city hospitals is not to be found in the surgical armamentarium. According to the ambulatory plan of treatment the use of the plaster splint is carried to a still greater state of perfection. It is claimed that the patient can get out of bed a few days after the accident, and can walk at the end of the first week, with the assistance of one crutch or a cane. About twelve years ago it became the custom of several surgeons in this city to encourage their patients to get out of bed as soon as possible, and often they would be able to walk on the injured limb at the end of a week or ten days. This plan, however, which only differed in a few details from the method now called the ambulatory, seemed to have fallen into disuse, in part perhaps due to the custom in our hospitals of handing over the treatment of fractured legs to the hospital internes, many of whom have habitually enveloped the limbs in rolls of cotton underneath the plaster. The ambulatory treatment as systematized at the present day consists in the use of a plaster splint snugly applied, without the use of cotton on the leg, but with this addition: that on the sole of the foot underneath the splint is placed a pad of cotton about three-quarters of an inch thick and slightly deeper at the heel. This splint grasps the leg firmly about the bony prominences, especially at the upper part of the leg and head of the tibia. The leg thus hangs suspended to a certain extent in the splint, the greater weight being borne on the bulging part of the leg below the knee, the sole of the foot being separated from the splint by the pad of cotton. The principle is the same as that taken advantage of in the use of an artificial limb, though, of course, the avoidance of pressure at the end of the limb is less perfectly accomplished. In a few cases this splint can be applied immediately before swelling has resulted. Generally, however, this is impossible and it is then wise to delay its application for four or five days, so that it may not be rendered unserviceable by the shrinkage of the limb. The short period of confinement to bed and the preservation of muscular nutrition are the main advantages of this plan of treatment, and as a result the general condition of the patient remains good and his period of invalidism is much shortened. It is not, however, a method adapted for all cases. In a considerable number the pain is so great that the patients cannot walk; in others, the weight

of the splint or timidity prevents locomotion. In some cases the shape of the upper part of the leg prevents proper support; in others the obliquity of the fragments is such that there is considerable risk of overriding and ultimate shortening, and in still others the laceration and contusion of the soft parts is too severe to warrant the early application of the splint. Experience seems to show that the ambulatory splint can be used with distinct advantage in from thirty to forty per cent. of simple fracture of both bones of the leg and in nearly all cases of fracture of the fibula. The same principle may be occasionally employed with advantage in the treatment of fracture of the knee though, of course, the apparatus must be of a different pattern.

One fact must not be forgotten in the trial of new methods, *i.e.*, that there is no class of cases, either in surgery or medicine, where the medical attendant is liable to meet unjust criticism or suits for malpractice as in cases of fractures where a perfect result has not been obtained. Caution, therefore, should be exercised in the employment of methods which have not received the general sanction of surgical authorities.

ANDREW J. MCCOSH, M.D.

ECHOES AND NEWS.

Dr. Welch Honored.—Yale University, on the occasion of its commencement in June last, conferred the degree of LL.D. upon William H. Welch, M.D., of Johns Hopkins University. Dr. Welch is an alumnus of Yale, and richly deserves this honor at the hands of his Alma Mater.

Dr. Doremus Appointed as Representative in Paris.—Professor Charles A. Doremus of New York has been appointed by Secretary Olney to represent the United States Government at the Congress of Applied Chemistry, which meets in Paris during the present month.

The University of Michigan Popular with the Orientals.—So many Japanese have received diplomas from the University of Michigan, that they have been able to organize and maintain an alumni association in Tokio, Japan. Two Chinese girls have recently had the degree of M.D. conferred upon them by the same institution.

A Strong Stand Against Popular Advertising.—The Austin-Flint Medical Society, at a recent meeting held at Hampton, Iowa, passed a resolution demanding that editors of lay papers in that district refrain from publishing notices of surgical operations, or other news matters containing the names of physicians.

In Memory of Dr. Loomis.—A large and very handsome tablet, bearing the following inscription, has been prepared by the Commissioners of Charities, and will be placed in Bellevue Hospital, New York:

"In Memory of Alfred Lebbeus Loomis, M.D., LL.D.
Born October 16, 1830—Died January 23, 1895.

A man of rare attainments. He had a strong will, untiring industry, and directness of purpose. These traits, with his well-ordered and resourceful mind, made him one of the ablest of his profession, and won for him its highest honors. He made many valuable additions to medical literature, and by his unusual powers as a teacher and practitioner of medicine, compelled the admiration and confidence of all who came in contact with him. This Hospital, especially, is indebted to him for thirty-five years of faithful work. By reason of his service in its amphitheater and in its wards, he added not only to its renown as a center of medical education, but to its glory as a refuge for the sick."

A Dispute Settled.—The dissension between the Medical Staff and the Board of Managers of the Ladies' Charity and Lying-in Hospital, Liverpool, England, has been adjusted at a meeting of the subscribers and results in a complete victory for the Medical Staff. The concessions insisted upon were entire charge of all patients by the medical officer on duty and a representation of three of the medical men in the managing board.

Revised Nomenclature of Diseases.—The committee appointed in 1892 by the Royal College of Physicians of London to revise the then authorized "Nomenclature of Diseases" has just completed the task and issued a volume of more than five hundred pages. The original edition was published in 1869, its preparation having occupied nearly twelve years. The present volume is so arranged that it will be a valuable guide to uniformity of nomenclature among nearly all of the more civilized nations, but is especially useful to English-speaking countries. Each disease is given first in English then follows the corresponding Latin, French and German names. Many important changes have been made in classification. This is particularly evident in diseases of the nervous, digestive, respiratory, and integumentary systems. The section on surgical operations has also been completely revised.

Cholera at Cairo.—The deadly virulence of the present epidemic is shown by the report made on July 2d. Of 7550, the total number of cases up to that date, 6216 had been fatal. A greater mortality (eighty-two per cent.) has seldom been observed.

An Official Report.—Mr. F. E. Moore, commercial agent of the United States at Weimar has officially reported to the State Department at Washington the results of the use of diphtheria antitoxin in the several German hospitals. His statements are in full accord with those already recorded in medical periodicals.

Remarkable Immunity.—In the recent retirement by the New York Board of Health of a long-tried and faithful em-

ployee in the person of W. J. Reynolds an instance of unusual freedom from contagion is brought to light. For more than twenty-three years it has been the daily duty of this man to personally attend to the removal of the victims, either dead or alive, of every contagious disease coming under the notice of this department. He was often compelled to carry in his arms the bodies of persons in all stages of the most infectious diseases, but always with perfect immunity to himself.

The U. S. Marine Hospital Service Warned.—Surgeon-General Wyman has received recent advices relative to smallpox in Cuba, which state that there are at least one hundred cases in the city of Santiago and that many families within a short distance of the U. S. Consulate are among the afflicted. The whole Southern coast of the island is a "plague spot of smallpox."

Honored in China.—The Order of the Double Dragon, carrying the rank of Mandarin, has been conferred upon Surgeon-Major Hueston of the British Army by the Emperor of China for services rendered the wounded during the Japanese war.

The Missouri State Medical Association.—This society, at its recent annual meeting in Sedalia, Mo., elected Dr. John H. Duncan, of Kansas City, president for the ensuing year.

The Chautauqua County Medical Society.—The annual meeting of this Society will be held at the Hotel Athenæum, Chautauqua, N. Y., Tuesday, July 14th, beginning at 11 A.M.

The Northern Tri-State Medical Association.—The regular annual meeting of this Society will be held in Angola, Ind., on Tuesday, July 21st. A long list of tempting and interesting papers is on the program.

The Cyclone as an Obstetrician.—The *Tri-State Medical Journal* is authority for the statement that in the recent cyclone that swept through the West with so much destruction, a young woman who was about to become a mother was sitting in her home, happy in the hope of the approaching event. The side of the house was blown off and she was carried by the storm across the street and landed on the opposite sidewalk. She became unconscious at the time the house was struck. When she recovered consciousness in her new location, the first sound that greeted her ears was the cry of a newly-born baby under her skirts. She gathered it up and called for help, which was promptly obtained. At last accounts both mother and baby were doing well.

The Parke Memorial.—The statue of the late Surgeon Parke, who so nobly supported the Stanley expedition in Africa, is nearly completed and will be unveiled during the early autumn on Leinster Lawn, Dublin. This is the first statue of an army surgeon to be erected in the United Kingdom and a just tribute to one who "loved his fellow-man."

Dr. Ferris as Acting Superintendent.—Dr. Albert Warren Ferris has been appointed Acting Superintendent of the private retreat for the insane at Pleasantville, N. Y., established by Dr. George C. S. Choate, who died June 28th. Dr. Ferris was for over five years the assistant physician and for a time acting superintendent of Sandford Hall, a similar institution in Flushing, N. Y.

Losses of the French Army.—The London letter of the *American Practitioner and News* states that according to an official account, the deaths of French soldiers from sickness in the Madagascar campaign greatly out-numbered those from casualties. While the enemy only killed 7 and wounded 94, 6000 died from disease, and 15,000 went on the sick list. This high percentage of mortality was eclipsed in 1802, in the Jawaca expedition, for out of 60,000 men who sailed from Brest, 50,000 died from yellow fever, and of the 10,000 men left, but 300 got back to France, and then only after a lapse of seven years. The 50,000 men died of yellow fever in four months.

The Congress of Dermatology.—The third International Congress of Dermatology will meet in London, from August 4th to 8th, of this year. The general program has been published in a recent number of this Journal. There will be a museum of drawings, casts, models, naked eye-preparations, microscopic specimens, works and atlases pertaining to diseases of the skin. There will also be an exhibition of clinical cases and demonstrations of the same, at 9 A.M. and 2 P.M. of August 5th, 6th, and 7th, and at 9 A.M. of August 8th. Anyone having anything to contribute to this department should address Dr. James Galloway, 21 Queen Anne street, Cavendish square, W. There will be an exhibition of cultures and microscopical preparations of organisms connected with the skin and its diseases. Any communications in regard to this department should be addressed to H. G. Plimmer, Esq., Wunderbau, Sydenham, London. The social side of the Congress will be: 1st, an informal reception at the International Hall, Piccadilly Circus, on August 3d, from 9 to 12 P.M.; 2d, a reception by the Lord Mayor and Lady Mayoress, at the Mansion House, on August 5th, from 9 to 11 P.M.; 3d, a dinner to the foreign members, at the Hotel Cecil, on August 7th. It is advised that foreigners should arrive in London not later than Sunday, August 2d, as Monday the 3d is a public holiday. Information in regard to hotels will be furnished on application to George Pernet, Esq., 77 Upper Gloucester place, London, N. W. George Thomas Jackson, M.D., is Foreign Secretary for the United States, and will furnish detailed information on application.

Smallpox as a Race Exterminator.—The Jenner centenary at Berlin was a great success, says the *Press and Circular*. The city authorities lent for the occasion the Festsaal of the city Rathhaus, and decorated it suitably to the occasion. About three hundred medical men took part in the commemoration, among them Dr. Bosse, the Cultus Minister, the Rector of the University, the Surgeon-general of the Army, with a number of the higher officials and several members of the Reichs-Gesundheitsamt. The medical faculty were nearly all present, and there were also deputations from nearly all the medical societies of the city. Professor Virchow opened the proceedings in

the name of the Committee of Honor. He said we lived in an era of reverence for the great benefactors of mankind. Of the number of these, as regarded the number of human beings saved, Jenner stood at the head. As an ethnologist he was impelled to mention an ethnological fact in the history of protective vaccination: "*All the peoples that had not been reached by vaccination, or that had not accepted it, had disappeared from the face of the earth, destroyed by smallpox.*" In the address of Professor Gerhardt appears the following, bearing on the thorough protection of German soldiers and the very imperfect protection of another foreign army: "The war of 1870 and 1871 furnished the most brilliant proof of the protective power of vaccination. Of the one and a half million of men composing the German army only 459 died of smallpox, while in the French army, vaccinated imperfectly or not at all, 23,400 men died of the epidemic of smallpox then raging."

CORRESPONDENCE.

HYDROTHERAPY IN THE TREATMENT OF TYPHOID FEVER.

To the Editor of THE MEDICAL NEWS:

DEAR SIR:—I note that Dr. W. J. Patek of Milwaukee, in criticizing, in THE MEDICAL NEWS, June 20, 1896, my article published in the NEWS of February 8, 1896, infers that I have "based my conclusions wholly on theoretical grounds," and that I have "evidently not had the privilege of coming in direct contact with typhoid patients, before, during, and after immersion." He also intimates that I am ignorant of the technic of the Brand treatment. Now, I am pleased to have any article discussed and criticized, but I would prefer the charge of deliberate misrepresentation to the insinuation that I would express an opinion on so important a matter without careful preparation, or on false pretenses of experience.

Naturally, in the typhoid patients who have been under my personal care—not a large number, as was admitted in the first paper, but several times the average quota of one working in a healthy city with a good water supply—immersion has not been practised. By addresses and journal articles, however, I am reasonably familiar with the utterances of most of the American and foreign advocates of immersion, though I must confess that there are so many minor differences among the various immersionists that it is a little confusing to select the orthodox method. It may be *evident* that I have "not had the privilege of coming in direct contact with typhoid patients before, during, and after immersion," but the fact remains, that I have witnessed quite a number of immersions, and have had the opportunity to watch the progress of a good many cases subjected to the treatment. At one time I found the mouth temperature of three patients immediately after the bath to be subnormal, and blueness, chilliness, etc., have been frequently observed. In fact, advocates of immersion concede these symptoms, but pass them over as "esthetic objections."

My critic is quite in error in intimating that I questioned the fairness of the statistics of my honored teachers, Professor Tyson and Professor Osler. My article had no reference whatever to their reports, but alluded to the fact that statistics in general are quite apt to be misleading and that, in the case of the new treatments of typhoid, diphtheria, etc., it is possible to obtain favorable percentages by excluding even the inevitably fatal cases which would not give a fair opportunity for any treatment, but which swell the general mortality.

Dr. Patek's observations that swimming baths of a duration, frequency, and temperature, approximately equivalent to those of the Brand treatment, have a beneficial effect on healthy persons, are the reverse of my own, but are all the more valuable on this account, since it is only by weighing the opinions and experiences of different observers that the truth can be obtained. His inference that my observations were modified by the compulsory nature of the baths is entirely incorrect.

Dr. Patek thinks it an error to consider the typhoid patient as an inert mass, and emphasizes the exercise which he obtains from rubbing himself and making movements in the water. Personally, I fail to see how even a healthy man can get, within the narrow confines of a bathtub, anything comparable to the invigorating exercise of swimming, and, time for time, or temperature for temperature, my endurance in the tub is much less than in deep water. However this may be, it is nonsense to suppose that a typhoid patient can or ought to make such movements as will render him, for practical purposes of comparison, anything more than an inert mass.

In conclusion, let me say that practical information is far superior to theorizing, yet there is such a thing as carrying pragmatism too far. The fact that the human body has great resisting power, does not warrant us in refusing to employ inductive reasoning, or properly limited analogies. Medical history has no darker pages than those recording the work of men who sneered at theories, disregarded general principles of humanity and therapeutic caution, and devoted their energies to amassing statistics.

A. L. BENEDICT, M.D.

BUFFALO, N. Y.,
June 27, 1896.

CARE IN HANDLING INFANTS.

To the Editor of THE MEDICAL NEWS:

DEAR SIR:—In THE MEDICAL NEWS of June 13th I read the "Practical Inferences from Clinical Observations in Lateral Curvature of the Spine," by A. B. Judson, M.D. I am much interested in Dr. Judson's practical writings; but the subject named affords me a text to announce my belief in one primitive cause of the "bending of the twig." Nurses and mothers, in many instances, when dressing and undressing or when bathing infants, handle them as if they could take care of their own heads, when in fact the untrained and undeveloped muscles have not the practice nor the power to support the head; consequently the head drops in whatever direction gravitation carries it when the child is held in a sitting posture. Muscles may thus be strained and retarded in their development so as not to overtake their mates on the opposite side. The head and shoulders of an infant should always rest horizontally on

the pillow or lap of the nurse, and its pelvis raised by grasping the feet while the clothing is removed and replaced over the feet instead of over the head. A child is no more able to support its head and trunk by muscular power than it is to stand or walk when it is born. Instrumental delivery may sometimes be a first cause. Whether the right-handed work of the schoolroom and the carrying of books is a more frequent cause than the carelessness of nurses, I am not prepared to answer.

N. W. LEIGHTON, M.D.

BROOKLYN,
June 22, 1896.

SOCIETY PROCEEDINGS.

THE AMERICAN SURGICAL ASSOCIATION, ANNUAL MEETING HELD AT DETROIT, MICHIGAN, MAY 26, 27, AND 28, 1896.

FIRST DAY.

The President of the Association, LOUIS MCLANE TIFFANY, M.D., of Baltimore, called the meeting to order, and read an address entitled

THE OPERATIVE TREATMENT OF TRIFACIAL NEURALGIA,

in which he stated that forty-five operators had participated in the hundred cases reported, of which number twenty-four had each operated upon one case only. He also mentioned that there was diminished sensation in these cases, and lessened lachrymation. He considered the curving of the tongue due to atrophy of the muscles, but did not understand why the perception of heat and cold should be interfered with. As to tying the carotids. Dr. Park of Buffalo had successfully done this in two cases.

DR. S. J. MIXTER of Boston, read a short paper in discussion of this subject, which was then thrown open for general discussion.

DR. W. W. KEEN of Philadelphia, was very much disappointed to learn that the mortality of operations for the relief of trifacial neuralgia was ten per cent. He had two deaths out of nine cases, one of which was due to sepsis and was avoidable. He explained the high mortality as being due, in his opinion, to the fact that the operations had been done by so many different operators, and thought that special operations should be reserved for those who have had some special training. In three of the nine cases mentioned, trouble was experienced with the cornea, but in no case was the eye lost. The following is Dr. Keen's method of dealing with corneal ulcer: Sew the lids together at the margin so as to prevent the opening of the eye, or take a circular piece of rubber plaster, cut out a circular hole in the center a little smaller than a watch glass, insert the watch glass in the hole thus made, and place this shield over the eye, the non-adhesive surface being next to the patient's eye. Although the rubber plaster does not absolutely occlude the whole space, yet the inside of the watch glass is always moist.

DR. J. EWING MEARS of Philadelphia, asked whether the President was clear in his own mind that the lesion exists in the Gasserian ganglion. If his experience with the operation upon the Gasserian ganglion demonstrates that the relief from pain is permanent, Dr. Mears felt that the real lesion had been discovered.

DR. GEORGE RYERSON FOWLER of Brooklyn, stated that in one of his cases there was a recurrence of pain, although he was absolutely certain that he had removed the ganglion. The necropsy showed the existence of a neuroma upon the stump in that portion which occupied the foramen rotundum. He fully agreed with Dr. Keen as to the necessity of keeping the eye protected, and mentioned an illustrative case. Concerning the sclerotic changes in the vessels, it may be that these are at the root of the pathology of these cases. Dr. Fowler referred to a case operated upon by Dr. Morton of Philadelphia, in which Meckel's ganglion was positively removed, and the pain returned with all its former violence in less than two years, when ligation of the common carotid gave the man permanent relief. The author mentioned other cases in which ligation of the carotid had produced excellent results, and in one of which there was a deviation of the tongue toward the side operated upon. In this case the patient was unable to straighten the tongue. He referred to one case which died during an epidemic of sepsis, and stated that he saw no reason why there should not be an epidemic of sepsis as well as of smallpox and scarlet fever.

DR. JOHN PARMENTER of Buffalo, mentioned the case of an elderly woman who had facial neuralgia, and also a small anurism of the external carotid, in whom ligation of the common carotid afforded complete recovery. He also cited a case in which he did an operation successfully on a man who had been subjected to three previous operations.

DR. H. S. WEEKS of Portland, doubted if a surgeon was justified in resorting to intracranial operations before an extracranial had been done in view of the large mortality. His plan is to trephine through the ramus of the jaw, seize the inferior dental nerve and pull it away, as he considers this method much better than cutting.

DR. N. P. DANDRIDGE of Cincinnati, cited a case on which he had operated two and a half years ago, since which time the man had been relieved from pain, but there was marked deformity of the face on account of atrophy of the muscles. There was also a small sinus leading down to dead bone.

DR. CHRISTIAN FENGER of Chicago, preferred the extracranial operation. as he considered it less dangerous. He called attention to the fact that the mortality from ligation of the common carotid was eighteen per cent.

DR. JOSEPH RANSOHOFF of Cincinnati, did not think ten per cent. a very high mortality under all circumstances, and said if all the cases were included, it would be nearer fifty per cent. In his opinion the lesion is not located in the Gasserian ganglion, but is a central affection.

DR. ROBERT ABBE of New York, said the members should not be daunted by a mortality of ten per cent., as in the next hundred cases it would be much less. In his opinion preference should be given to an anterior opera-

tion in the first place. Now that we know what we are to steer clear of, with the improvement in asepsis and the avoidance of operating on old people, the mortality should be considerably lessened.

DR. W. W. KEEN said he had ommitted to mention two methods of medical treatment which had been of great service, one recently suggested by Dr. Dana of New York, that of giving massive doses of strychnia, and the other was suggested by Esmarch, who has spoken of the value of purgatives.

DR. MAURICE H. RICHARDSON of Boston, believed that attacking the ganglion should be done as a last resort, especially in old people, and those who were unable to stand so formidable an operation as intracranial neurectomy. In many cases a simple operation would give considerable relief.

DR. FOWLER explained that the mortality of eighteen per cent. in ligations of the carotids, included cases of anurism, gunshot wounds, etc. In fifty two cases where the vessels were not affected by disease, nor complicated by carcinomatous tumors, the mortality was less than five per cent.

DR. P. S. CONNER of Cincinnati, said the two most important points were the cause of the neuralgia and the results of operative interference. In a certain proportion of cases the exemption from pain ranged from three months to three years, while in another proportion the exemption was scarcely worth mentioning, as the pain returned immediately after the operation. In some cases the loss of blood during the operation and the shock from the operation had caused periods of freedom from pain. The propriety of the operation had been established, as a man would rather take forty-nine chances out of fifty to get relief.

DR. T. A. MCGRAW of Detroit, was of the opinion that sufficient investigation had not been made of the possibility of the neuralgic conditions being due as well to motor as to sensory nerves, and stated that he was not at all sure that a division of some of the motor nerves might not be a great benefit.

DR. RICHARDSON stated that this operation had been performed and resulted in considerable facial deformity, but no relief of the neuralgia.

DR. MIXTER mentioned two cases in which merely reopening the old intracranial wound had afforded some relief.

The afternoon session was wholly given up to a consideration of

THE SURGICAL TREATMENT OF TUBERCULOSIS OF THE SOFT PARTS.

The first paper on

TUBERCULOSIS OF THE MALE GENITO-URINARY APPARATUS,

by NICHOLAS SENN, M.D., of Chicago, was read by title.

ALBERT VANDER VEER, M.D., of Albany, presented a paper upon

TUBERCULOSIS OF THE FEMALE GENITAL ORGANS (INCLUDING TUBERCULOSIS OF THE KIDNEY).

He stated that this subject had been neglected until recent years, and that the modern ideas and progress depended upon careful histological and bacteriological examinations. Tuberculosis of the female pelvic viscera was not limited to any age, the extreme limits being ten weeks and eighty-three years. External genital lesions might be confounded with tuberculosis. Heredity was important as suggesting tubercular possibilities. Tuberculosis was extremely rare in the external genitals, but by no means infrequent in the uterus. Tuberculosis of the uterus could be demonstrated by microscopic examination of the discharges and by curetting. Gonorrheal infection was often grafted upon tuberculosis. Sometimes infection took place through the fingers or the instruments or the semen. Tuberculosis originated in the tubes and infected the uterus and cervix. The uterus could be infected from without or within, and the infection was aided by a lacerated cervix, pelvic peritonitis, trauma, etc. The symptoms were local irritation, a pea-sized wart near the vaginal outlet, a discharge from the uterus, etc. The differentiation between the ulcers of syphilis and epithelioma depended on age, history, local appearances, etc. Tuberculosis of the cervix might be mistaken for cancer. Many vaginal cases were infected from the tubes, and tubercular peritonitis might infect the vagina and tubes. The author mentioned several cases illustrative of the points mentioned.

With regard to tuberculosis of the kidney, there were two forms: (1) miliary tuberculosis, and (2) caseous or true tuberculosis. The author gave the details of one or two cases and referred at some length to Kelly's nephroureterectomy.

ROBERT ABBE, M.D., of New York, read a paper upon

TUBERCULAR PERITONITIS.

In reviewing this interesting subject, Dr. Abbe thought it gave a fairer understanding of the multiform appearances of the disease if we viewed it from the standpoint of the bacillus, rather than as others have done from the gross appearance, which had led to the division into the ascitic, the dry and the caseating forms. A sudden tubercular eruption into the peritoneal cavity may be as acute in symptoms and durations as peritonitis from other causes. A slower outbreak may result in ascitic distention in three or four weeks, and a less virulent bacillus may occupy months in inducing ascites and wasting. In other cases, possibly due to the route of invasion (penetration through lymphatics communicating mucous and peritoneal serous coats or by follicular ulcers—admitting tuberculous milk to be the median of infection), a dry or adhesive form follows in which hectic and rapid wasting result. Again, the bacillus produces an outpouring of thick lymph and flocculent serum, which rapidly becomes purulent, producing unsymmetrical cakes of thickened omentum, matted coils and encapsulated purulent collections. The bacillus product rapidly caseates and ulcerating fistulæ may result. All phases of the disease may be regarded as representing the life history of the bacillus and its products. Tubercular peritonitis may be, and in the early stages often is, the only site of tubercle deposit in the patient, hence, if overcome here a practical cure often follows. Even when other phases of infection

(pleural, intestinal, bronchial) are seen, an operative cure of the peritonitis has often been followed by general recovery. The mode of entrance of the bacillus is directly through the intestinal wall or through ulcerating appendicitis or tubal or ovarian tuberculosis, or through the blood. The claims of a few recent authors to having cured tubercular peritonitis by medical treatment were reviewed and credited. The unquestioned cure of true tubercular peritonitis by laparotomy was proved by two classes of cases, those who have long survived operation, and those who have come to autopsy long afterward, have been found free from tubercles that studded the peritoneum at the time of operation. Experimental proof in animals corroborates, also operation by simple laparotomy and evacuation of the ascites. Closing the dry abdomen is credited with a large number of cures. Irrigation with warm salt solution is advocated by preference. Camphor-naphthol application, as used by Rendu, is advised for bad cases. Dr. Abbe reviewed many interesting and illustrative cases in speaking of direct medication. The many theories advanced to account for the surprising cures were carefully considered, and it was said in conclusion that the theory that is sustained by most facts was that based on the life-history of the bacillus and the capacity of the animal economy, not only to suppress the activity of the organism by encapsulating it, but to remove it by absorption. The proper opportunity for conquests is not afforded in the presence of ascitic fluid, which acts as a veritable culture bouillon, and by its fluidity aids dissemination. When, however, the peritoneum has been aroused by congestion, which follows evacuation, and a reactionary inflammation is set up, engendering cell hyperplasia, the intruder is walled in and retrograde degeneration will begin.

GEO. RYERSON FOWLER, M.D., of Brooklyn, continued the general subject by a paper on

INTRATHORACIC TUBERCULOSIS.

He went into the historical part of the disease at great length, and devoted considerable attention to the surgical treatment of pleuritis and empyema. Of all the organs in the human body the lungs are most frequently the seat of these affections. Inasmuch as there is no lung affection that cannot be complicated by tuberculosis, it follows that pleural affections are most frequently tuberculous in character. Few patients who have suffered from pleurisy escape tuberculosis, and this fact increases the importance of the surgery of pleuritic affections in their relation to tuberculosis. The author gave a brief discussion of the effects of the presence of the pleuritic effusion upon the progress of tubercular disease of the pulmonary structure. The view formerly held that the activity of the circulation in the lung tissue constituted a trustworthy means of protection against the occurrence of tubercular infection of the respiratory organs was combated, and reference was made to the observations of Laennec, who, in the early history, stated that stasis was incompatible with the progress of pulmonary tubercular affections, and Bier's observations, supported by those of Miller, in the treatment of tubercular joint disease by means of a constricting bandage was held to confirm the views of Laennec in this particular. Note was taken of the fact that in any pleuritic affection, even when due without doubt to tubercular affection, the effusion is found to be serum, the suggestion follows that this effusion possesses some resisting influence over the development of the tubercle bacillus, while it undoubtedly forms a favorable culture medium for other organisms. The application and technic of exploratory puncture or thoracentesis, incision, and drainage, and Koenig's operation, the resection of a portion of rib, were gone into quite extensively. This was followed by a consideration of the operation of thoracoplasty and its indication. Schede's operation for extensive resection of the chest-wall, including with the bony resection removal of the attached soft parts, namely, the intercostal muscles and thickened pleural membrane, was described. It was recommended that the edges of the incision should be approximated closely about the drainage-tube and the dressing should be applied in such a manner that the tube passes through these. The drainage-tube is then attached to a tube sufficiently long to lay over the side of the bed and touch the surface of a sublimate solution. When the patient can sit up the tube is fastened to a bottle at the waist, as suggested by Bulau of Hamburg. By this method of drainage the patient is saved from the discomfort produced by soiled dressings. The question of complications occurring in connection with thorocoplastic operations upon the chest-wall, namely, pulmonary thrombosis, cerebral embolism, and the resulting paralysis, was alluded to. The concensus of opinion at the present day was thought to discountenance thoracotomy in tubercular patients, preference being given to repeated puncturing or at the most the method of permanent siphonage.

The question of the direct treatment of tubercular cavities was entered into quite extensively, and it was stated that some difficulty must necessarily be experienced in the selection of proper cases. In cases in which the disease had come to a standstill, any interference would be unjustifiable, for the reason that it is these cases that undergo cure by natural processes. In addition to limiting operations on tubercular cases to those that are circumscribed, the operation may be applied to certain cases of a doubtful nature, which form at the expense of both pleura and lung, namely, pulmonary abscesses secondary to tubercular caries of the ribs. Three examples of this were quoted. The operation of resection of the lung was discussed at some length, and attention was called to the fact that the pulmonary structure differs from all other structures in the body in its susceptibility to infection and its anatomical peculiarities. The experiments of Glück of Berlin, and Hans Schmidt, upon the lower animals for resection of the lung were detailed, as also those of Virondi, who produced localized tuberculosis in the lower animals.

DEFOREST WILLARD, M.D., of Philadelphia, read the next paper, entitled

TUBERCULOSIS OF THE SUPERFICIAL GLANDS.

He first detailed the method of tubercular infection of the lymph nodes. The route of entrance is usually by very slight abrasions or injury. Slight wounds are more liable to admit bacilli, as they arouse local resistance to a

less degree than more severe injuries. The face and neck are especially common routes of entrance. The lymph glands act as filtration stations, and often prove effective in overpowering the invading foe. They are liable to be successful in proportion to their amount of resistive force. An individual's resistive force may be lessened by hereditary impairment of cells, or by the condition of the tissues.

Local karyokinetic action may be successful, or if partially successful caseation and absorption may occur with less resistive power, or if staphylococcus infection results, suppuration follows. When once the glands have become infected, they are a perpetual menace to the general system, and should be removed. Suppuration will sometimes effectually destroy all the invading bacilli, yet this is a slow and dangerous process, subjecting the individual to constant risks.

Infected glands should be removed, if possible, during the stage of induration.

The removal of tubercular glands from the neck is frequently a most serious operation, provided connective infiltration is present, and especially if the chain of glands has dipped deep beneath the cervical vessels and nerves or has extended below the clavicle. These deep glands can only be safely removed by following the line of cleavage between the gland and the protection wall, which has been partially thrown about it, each gland being cautiously shelled out.

The jugular veins, the branches of the carotids, and the pneumogastric and phrenic nerves should be carefully avoided. When a vein is injured, immediate pressure, with subsequent ligation or lateral suturing, should be performed. If the phrenic or pneumogastric are injured, they should be at once sutured with fine silk.

Great care should be exercised to prevent the discharge of pus and caseating material upon the fresh wound; if such accident occurs, the area should be thoroughly cleansed and disinfected. Temporary drainage is advisable when infection has occurred from such discharge, but in healthy operations, with clean enucleation, primary union without drainage can be secured.

In infection in the axilla, the glands should be enucleated with the same care that is employed in the removal of carcinomatous nodule. The same rule holds good in regard to glands situated in other portions of the arm. In the groin, many difficulties will be encountered, especially if the indurated glands extend deep about the femoral or saphenous veins. Secondary operations are advisable, if necessary. In cases that absolutely refuse operation, local and constitutional measures must be employed, including tuberculin and serotherapy. The author has more confidence in the local effects of iodin upon tubercular granulations than in iodoform. He has also had beneficial results from stimulation of cell growth by a mixture of aristol with nuclein or protonuclein, applied locally. Tubercularly infected glands should not be allowed to remain and contaminate the general system.

Short papers on this discussion were read by Drs. J. McFadden Gaston of Atlanta, Chas. B. Nancrede of Ann Arbor, J. R. Weist of Richmond, Ind., and Geo. W. Gay of Boston.

Second Day.

Albert T. Cabot, M.D., of Boston, opened the proceedings of the day by reading his paper upon

Does additional experience show that castration is a curative remedy in the treatment of hypertrophy of the prostate gland?

He drew the following conclusions:

1. In the matter of mortality, the operation of prostatectomy has a slight advantage over castration. It seems probable that with later statistics, reflecting the last improvements in the technic of prostatectomy, this advantage would be further increased.

2. Prostatectomy had the further advantage that it allows of a thorough examination of the bladder and of the discovery and correction of other conditions not before suspected. Stones are frequently removed in this way without adding to the gravity of the operation. In several reported cases of castration, the absence of improvement has led to subsequent discovery of stones, which have required other operations for their removal.

3. Prostatectomy has, on the other hand, the disadvantages that it confines the patient for a longer time, and that it is sometimes followed by a fistula. This occurred in one of the forty-two cases cited in this paper.

4. It is too early to know whether any permanent loss of vigor follows castration when done on old men. The nervous effects which sometimes immediately follow the operation suggest a suspicion that with the testes the system may lose some tonic effect exerted by those organs.

5. The functional results of the two operations seem at present to be as nearly equal as possible, and the tendency to relapse shows itself in about the same proportion of cases after either operation.

6. The reduction in the size of prostate after castration is largely due to a diminution of congestion. Later a degeneration and absorption of considerable portions of the gland may occur. The glandular elements are particularly affected by this atrophy.

7. Castration would seem to be especially efficacious in cases of large tense prostates when the obstruction is due to pressure of the lateral lobes upon the urethra.

8. Castration is of but little use in myomatous and fibrous prostates.

9. Prostatectomy has its especial field in the treatment of obstructing projections which act in a valvular way to close the urethra. There is, however, no form of prostatic obstruction which a skilful operator may not correct by prostatectomy.

10. Prostatectomy is then applicable to more cases than castration and is especially to be selected when an inflamed condition of the bladder makes drainage desirable.

Dr. J. Ewing Mears of Philadelphia, was very much struck with the mortality shown from the different operations. He was sorry to learn that no one had any information to offer concerning an operation suggested by himself as a substitute for castration, namely, ligature of the vas deferens.

Dr. Chas. B. Nancrede of Ann Arbor, said that as

a result of his work with the operation of castration, he had been converted from a rather doubtful attitude toward the operation to a desire and willingness to do it again. He gave at some length the details of the case operated on by himself, which did very well after the operation, but the patient died in five or six weeks from an infection of his wound.

DR. L. S. PILCHER of Brooklyn, said that from the statistics mentioned in Dr. Cabot's paper, it would seem that prostatectomy had a slight advantage over castration, not only in its results but also by affording opportunity to secure relief from other urinary complications at the time of operation. In his own hands, however, all prostatectomy operations had been failures, but if the opinions of other surgeons could be ascertained, it would probably be found that a much larger proportion of fatal results really occurred than the figures mentioned by Dr. Cabot showed. The operation of prostatectomy has only been resorted to in cases of men who manifested considerable vigor, while on the other hand, castration has been performed in cases that were already extremely feeble, and could not stand a more serious operation, and frequently by surgeons who were not particularly expert in genito-urinary work.

DR. J. MCFADDEN GASTON of Atlanta, spoke of a method of treatment that had recently been brought to his notice by a gentleman whose name he would not mention, the principle of which was to endeavor to reduce the size of the prostate by the employment of prostatic extracts in a somewhat similar way to the methods now employed with the thyroid extract.

DR. ROSWELL PARK mentioned two cases of castration performed by himself in which the subsidence in the volume of the prostrate gland was remarkably rapid and complete. In his opinion there could not be a simpler or easier operation.

DR. ROBERT ABBE spoke of one case in which he had removed both testicles under cocain, with the result that the prostate was reduced more than one-half its size. He compared the operation of castration to that of removal of the ovaries.

DR. CABOT said the most important question was not the ability of the operator, but the selection of the proper cases for the operation of castration. If a proper selection was made, he believed the mortality would be greatly reduced.

LOUIS S. PILCHER, M.D., of Brooklyn, read the next paper upon

THE AMBULATORY TREATMENT OF FRACTURES OF THE LOWER EXTREMITIES.

DR. PILCHER mentioned a large number of cases of fracture in which the ambulatory treatment had been employed, and illustrated his paper with diagram of the apparatus employed. He described in detail the manner of applying the plaster bandage so as to form a sufficiently rigid and protective case, and also explained the splints used in this method of treatment. He stated that the number of cases of fracture of the leg treated by himself up to the present time with the ambulatory dressing was twenty and the results that have followed this treatment in these cases have been very satisfactory.

DR. JOHN E. OWENS of Chicago, stated that cases of fracture of the lower extremity treated by this method might be divided into two classes, first, those that walk with the aid of crutches, but bear little or no weight upon the affected limb, and second, those that walk on the affected leg with or without the aid of cane or crutch. After describing at some length his method of applying the dressing, demonstrating the apparatus in position and referring to cases in which he had used it, he concluded: (1) That the main object in the treatment is to enable the patient in a few days to get up and walk about on the fractured leg. (2) That union is accelerated in many cases; comfort, appetite, digestion, and sleep secured; swelling, muscular atrophy, pneumonia and delirium tremens prevented and flexion and extension maintained. (3) That in the application of the dressing the foot is maintained at a right angle to the leg, and extension maintained until the deformity is corrected and the legs are of even length. (4) That the material usually employed is plaster-of-Paris in which wooden or metal strips may be included, there being a very thick plaster sole, separated from the foot by a layer of cotton about five centimeters thick, the plaster being carefully molded with the hand, so as to fit snugly against the upper end of the tibia and about the dorsum and ankle. (5) It is generally thought best not to apply the dressing until the second or third day after the accident. (6) The patient must remain under observation in order that any displacement, undue constriction, or other defect may be noted. (7) In fractures of the thigh a combination of plaster-of-Paris and glue is recommended by some, while others have used special splints. (8) The plaster may be made to include the pelvis. (9) The dressing may be applied to the leg, and then allowed to harden after which the patient's hips are raised from the bed, extension being made to correct displacement and the remainder of the dressing applied. (10) An important feature of the dressing is its strong reinforcement and close application at the upper and back part of the thigh, thus securing a firm bearing against the ischium and perineum. (11) That the sooner the immobilization is affected the less will be the swelling. (12) That the method can be applied with great satisfaction, and that an exact fit must be secured.

DR. N. P. DANDRIDGE of Cincinnati, briefly discussed this paper.

DR. CABOT said that in two cases the use of Dr. Pilcher's apparatus had been a benefit in his hands.

DRS. SENN, WILLARD, FENGER, MEARS, NANCREDE, and GAY, did not agree with the methods of treatment suggested by Drs. Pilcher and Owens.

DR. H. H. MUDD of St. Louis, thought the apparatus might work very well in certain cases.

DR. MOORE stated that he had had good results from the employment of this method of treatment in two cases.

W. W. KEEN, M.D., of Philadelphia, read a paper on

THE TREATMENT OF TRAUMATIC LESIONS OF THE KIDNEY.

After reading a tabulated list of 163 published cases of renal traumatism since 1878, the author stated that traumatic lesions have, as a rule, two advantages over the

other renal affections: (1) being apt to be unilateral, the other kidney is not injured; and (2) the injured kidney is apt to be healthy or fairly so. Gunshot wounds, on the contrary, have two disadvantages; (1) that the treatment of the kidney alone, in many cases, cannot be solely considered; and (2) if the renal substance is only moderately injured, no one would be willing to do primary nephrectomy.

As to the treatment of gunshot wounds, they may be divided into; (1) those involving only the renal substance; (2) those involving the pelvis; (3) those involving the vessels, and (4) those involving the ureter. The incision in most cases should be abdominal, either median or at the outer border of the rectus, and if the vessels are badly torn so that there has not only been a great deal of hemorrhage, but the integrity of the organ is threatened, nephrectomy should be performed.

In treating the exravasated blood in case the kidney is not removed, if the bleeding is into the peritoneal cavity, the blood must be removed by abdominal section, but if it accumulates in the perinephritic tissues alone, it may be left undisturbed.

In treating the kidney, if the wound is sufficiently large for it to prolapse, it should be sutured and replaced if its condition is suitable, and the same procedure may be carried out if the pelvis of the kidney is opened. A partial nephrectomy would be advisable if a portion of the kidney is so far severed that its future integrity is threatened, and the fragment removed.

As the dangers of rupture of the kidney are primary and secondary, the treatment may be conveniently so divided. Usually it must be decided if a nephrectomy shall be done within the first few days or even hours, but it may occasionally be postponed and become a secondary operation, while the lumbar route will be best.

Of 116 cases of rupture of the kidney reported, 66 recovered. Secondary nephrectomy is nearly twice as fatal as primary.

ROSWELL PARK, M.D., of Buffalo, presented a paper upon

ON SUSCEPTIBILITY AND IMMUNITY, WITH SPECIAL REFERENCE TO SURGICAL CASES. (To appear in an early issue of the MEDICAL NEWS.)

DUDLEY P. ALLEN, M.D., of Cleveland, presented a paper entitled

THE EFFECT OF ANESTHESIA UPON THE TEMPERATURE.

Dr. Allen dwelt very fully on the results obtained from a large number of experiments, principally upon dogs, and gave the details of each observation.

DRS. GAY, PARK, HARTE, FENGER, WILLARD, ABBE, MCGRAW, and NANCREDE heartily endorsed Dr. Allen's methods and views.

Dr. Park, representing the Committee on the Nomenclature of Tumors, presented a printed report showing the method suggested by the Committee of Classifying Tumors.

DR. J. MCFADDEN GASTON of Atlanta, demonstrated upon the cadaver, an improved method of exploring the thoracic cavity.

DR. S. H. WEEKS presented his report as a delegate to the British Medical Association in 1895.

CHRISTIAN FENGER, M.D., of Chicago, read a paper on

RETENTION FROM BENDING AND VALVE FORMATION (OBLIQUE INSERTION) IN THE BILIARY TRACT.

He demonstrated, by morbid specimens and diagrams, his method of treating this affection.

JOSEPH RANSOHOFF, M.D., of Chicago, read a paper entitled

AN UNUSUALLY LARGE PERIOSTEAL SARCOMA OF THE THIGH SUCCESSFULLY TREATED BY EXTIRPATION.

This paper was discussed by Drs. Dandridge and Gaston, who mentioned cases somewhat similar to that of Dr. Ransohoff.

DR. J. COLLINS WARREN of Boston, was elected president for the ensuing year, and Washington was selected as the place for meeting in 1897.

REVIEW.

A HANDBOOK OF MEDICAL DIAGNOSIS FOR STUDENTS. By JAMES B. HERRICK, A.B., M.D., Adjunct Professor of Medicine, Rush Medical College; Professor of Medicine, Northwestern University Woman's Medical School, etc. With 80 illustrations and 2 colored plates. Philadelphia: Lea Brothers & Co., 1895.

STANDARD manuals of diagnosis are not quite so numerous as books on many other subjects in medicine, hence the appearance of a new one arouses considerable interest. The one before us is somewhat smaller than the work of DaCosta and Musser, but much larger than the usually unsatisfactory books belonging to the class of compends. Following in its classification the plan of the newer works on the practice of medicine, it takes up, in a very thorough manner, the symptoms and differential diagnosis—the latter, where possible, in tabular form—of the entire list of diseases to be found in the most recent works. The various chemical tests introduced into clinical studies are given, and we would especially commend the section on urinary analysis. Perhaps a few words on the pentoses might have been added to the chapter. On page 299 we find a slight error to be corrected in a future edition—exogenic-torticosis should be exogenic toxicosis. The chapter on diseases of the blood is very good, and the most approved methods of staining are given. Diseases of the nervous system receive thorough treatment, and the text is helped by a number of well-chosen illustrations. The book will, we believe, hold in the English language the same rank that is occupied by Klemperer's excellent work in Germany.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 13, 1896.

June 6th.—Passed Assistant Surgeon P. H. BRYANT, ordered to Naval Station, Newport, R. I.

Assistant Surgeon C. M. DEVALIN, detached from the Chelsea (Mass.) Hospital and ordered to the "Blake."

June 13th.—Passed Assistant Surgeon E. R. STITT, detached from the "Blake" and ordered to the "Vermont" June 15th.

POST-OPERATIVE INTESTINAL OBSTRUCTION.[1]

BY EUGENE BOISE, M.D.,
OF GRAND RAPIDS, MICH.

I SHALL, in this discussion, exclude all forms of intestinal obstruction that are not direct results of operation, and shall consider post-operative obstruction under two main forms—functional and organic. Under the term functional I shall include two opposite conditions: Tonic spasmodic contraction of the muscular coat of the intestine, and that condition properly designated paralysis. Under the term organic I shall discuss only that form of obstruction caused by adhesions, omitting those that are accidental, as volvulus, incarceration, etc.

In the majority of cases, intestinal obstruction occurring after abdominal operations is due to adhesions, either existing prior to operation and remaining unrelieved, or those which form as the direct result of the conditions caused by the operation. The clear indication in pre-existing constricting adhesions is to separate them at the time of operation. The equally clear indication in the second group is to leave the abdominal and pelvic cavities in such condition as to reduce to the minimum the liability to post-operative adhesions. How to secure this end has been, still is, and will continue to be the object of discussion.

We have, then, post-operative intestinal obstruction occurring:

1. As tonic muscular spasm.
2. As true intestinal paralysis.
3. From the formation of new adhesions.
4. As a result of pre-existing constriction not discovered or relieved at the time of operation.

That we have post-operative obstruction as the result of tonic intestinal spasm is, I believe, not generally recognized, but this condition may, and often does, occur as the result of violent stimulation of the muscles of the intestine. Landois and Stirling[2] say: "All stimuli applied to the plexus mesentericus increase peristalsis . . . which may even produce spasmodic contraction of the musculature of the intestine." Murphy relates a case[1] of lead-poisoning with absolute obstruction, which had continued five days, and in which operation revealed tetanic spasm of the muscular coat of the small intestine for a space of eight inches, so severe as to cause entire obliteration of the canal. This spasm, however caused, may persist till death. Ashton[2] relates two cases where this condition was revealed at the autopsy, one case occurring in his own practice, where death occurred on the fifth day. Autopsy revealed a tonic contraction of the small intestine for a space of about eight inches above the ileocecal valve, the canal being rendered impermeable. There were no adhesions and no signs of peritonitis. His second case was reported by Dr. Baldy, following hysterectomy. The abdomen was reopened on the sixth day, but death resulted twenty-four hours later. Autopsy revealed no peritonitis, no adhesions, but "the intestine was contracted in one or two places so as to feel like hard cords."

Intestinal peristalsis is directly under the control of the sympathetic system of nerves, and is influenced in two ways: (1) By stimuli applied to the motor nerves at their origin, during their course, or at the terminal ganglia in the muscles themselves; and (2) by agencies which influence the vascular supply. Stimulation of the motor or vasomotor nerves causes increased peristalsis; over-stimulation causes spasmodic contraction, which may become tetanic.

As shown in the case cited by Murphy, lead-poisoning may cause tetanic contraction of the intestinal muscles, because of the direct irritant action of the poison on the nerves controlling these muscles. Other poisons have a similar action. Excessive electrical stimulation will produce the same condition; and the cases reported by Dr. Ashton show that there are conditions resulting from operation that will cause the same result. In the consideration of the question as to what these conditions are, we must bear in mind the nervous mechanism of the intestinal muscles; that the nerves belong to the sympathetic system and arise from the various abdominal plexuses; that these nerves terminate in a fine network of ganglionic cells, known as Auer-

[1] Candidate's paper, presented for admission to the American Gynecological Society, May, 1896.

[2] *Jour. Am. Med. Assn.*, July, 1892.

bach's plexus, situated in the muscular tissue itself; and finally that an irritant applied to the mucous lining of the canal, to its serous covering, to the nerves in their continuity, or to their origin in the various plexuses, will cause muscular contraction, and that the severity of this contraction will be proportionate to the nature and severity of the irritant impulse. This, I may say, is the keynote of the pathology of intestinal obstruction from tonic spasm. This irritant impulse may be direct, it may be reflex, or it may act through the vasomotor nerves of the intestines.

Brunton and others, by accurate experiment, have determined the fact that excess of venous blood in the intestine excites peristalsis. Therefore, any impulse that causes contraction of the arterioles, and consequent arterial anemia, causes increased peristalsis. It therefore follows that tonic spasm of the intestine may be brought about by excessive irritation of the motor nerves governing the intestinal muscles, and that this spasmodic impulse may be aggravated or exaggerated if, at the same time, the vasomotor nerves of the intestinal vessels are irritated.

There is always more or less violence to the motor mechanism of the intestinal canal during severe operations within the abdominal cavity. This violence necessarily acts as an irritant to the nerves and muscles of the intestines and causes exaggerated and irregular peristaltic action, which may be so severe as to cause intestinal obstruction by tonic spasm. This condition has been often mistaken for paralysis, but the term intestinal paralysis should be restricted to that condition of the intestinal muscle where its contractility is destroyed, the tube being dilated, rather than contracted. It may occur as a result of "muscle tire,"[1] following the excessive muscular action described above, as a result of any factor that causes pathological infiltration of the intestinal walls, or as the direct result of section of the nerves.

The first condition, muscular exhaustion, need not be dwelt upon, as it is properly an extension or sequel of excessive muscular action. The second condition may arise (1) from peritonitis, sepsis, etc., and (2) from any cause that cuts off the arterial blood-supply, as thrombus, volvulus, etc. Maas[2] relates a case (not following operation) where the intestinal wall for a space of several feet was thickened and infiltrated with pus, causing fatal obstruction. The direct cause of the infiltration was not demonstrated, but in the absence of signs of peritonitis, was thought to be due to thrombus of an artery.

Stumpf, of Munich, in a paper read before the sixth session of the Deutsche Gesellschaft für Gynæcologi, at Vienna,[1] mentions expressly as one of the factors of "Darmlähmung" eventration of the intestines. Freund, in the course of the discussion of this paper, laid special stress on eventration as a cause of intestinal paresis, but stated that, in his opinion, the cause of ileus was due, in the majority of cases, to general or circumscribed peritonitis. Some writer has stated that eventration causes a serous infiltration of the walls of the intestine, and consequent muscular paralysis. However that may be, it is probable that eventration, or long exposure of the intestines to the air, may cause true paresis in many cases, and that the effect of such exposure tends in all cases toward paresis, rather than toward spasm. We are confirmed in this belief by the combined testimony of operators, by the case of Dr. Murphy, above cited, where a spasmodically contracted intestine, which had caused total obstruction for several days, rapidly relaxed when exposed to the air, and by the fact that intestines exposed to the air for any considerable length of time become distended with gas. Again, I can conceive that bruising of the intestinal wall, as by violent and injudicious effort to release adhesions, may cause direct muscular paralysis. However this may be, we still have as operative causes of functional intestinal obstruction, severe irritation of the nerve supply, causing persistent tonic spasm, and local or general peritonitis, obstruction of arterial or nervous supply, and eventration, causing true paralysis.

Organic obstruction may be caused by pre-existing bands or by post-operative adhesions. Those adhesions that exist prior to operation are due to former peritonitis, and should be released at the time of operation. They therefore merit no further discussion in this connection.

But it is a very pertinent question, how shall we reduce to the minimum the liability to the formation of adhesions after operation? A tendency to adhesion is a peculiarity of serous membrane; and yet, as long as the integrity of its epithelium is preserved, it will remain in close contact with an opposite intact serous surface with no tendency to adherence. It would therefore appear that the one important indication is to preserve the epithelium intact to as great an extent as possible. In making a diagnosis in cases of post-operative intestinal obstruction, it is

[1] "Landois and Stirling," p. 318.
[2] *Annals of Gynecology*, February, 1895.

[1] *Centralblatt für Gyn.*, June, 1895.

practically only necessary to differentiate between functional obstruction and organic, inasmuch as such decision indicates the line of treatment. In making this diagnosis, we shall be obliged to rely mainly upon the history of the case, inasmuch as the symptoms of obstruction vary very little, whatever the cause.

After nearly all abdominal operations, even of moderate severity, there is transient obstruction, the evidence of which is intra-abdominal pain, more or less spasmodic in its nature, and generally referred to a point at or near the seat of the greatest violence. This may be caused, in part, by the constricting ligature about the stump, but is largely caused by irregular, exaggerated (or even spasmodic) peristaltic action, an effort on the part of normal intestine to overcome obstruction at this point. This obstruction, in the absence of any history of prolonged exposure of the intestines, or of partial preëxisting obstruction, may fairly be attributed to intestinal spasm, which, undisturbed, always tends to speedy relaxation, with reëstablishment of normal peristalsis. If, however, this condition be aggravated by injudicious treatment, tetanic contraction may occur, which may persist till death, or it may give rise to actual, fatal intestinal paralysis, the result of muscular exhaustion. If there has been eventration of the intestines, or prolonged exposure to the air, the conditition may well be, from the first, paresis of that portion of the bowel so exposed with exaggerated peristalsis of the healthy intestine. Or if the symptoms only show themselves with the onset of peritonitis, the condition is one of true paralysis, due to involvement of the muscular coat in the inflammatory process. In intestinal paralysis we should expect more or less gaseous distension. In tonic spasm this would probably be absent till a condition of muscular exhaustion ensued.

Again, if several days have elapsed before the symptoms of obstruction show themselves, especially if for a longer or shorter period flatus has been passed, and if there is an absence of signs of peritonitis or sepsis, we may be confident that we have to do with organic obstruction due to post-operative adhesions. Like the occurrence of post-operative hemorrhage, the question as to obstruction is largely decided at the time of operation, and our discussion of the treatment must involve to a certain extent a discussion of technic. It is important, therefore, in making an abdominal operation, that we continually keep before our minds not only those conditions that predispose to hemorrhage and sepsis, but equally those that tend to impairment of function of the intestinal canal.

Inasmuch as irritation of the motor nerves at their origin, in their continuity, or at the terminal intermuscular plexus, tends to promote excessive contraction of the muscles; and inasmuch as *severe* irritation may cause tetanic contraction, it follows that we should, during the operation, use all possible precaution that we may reduce to the minimum such irritation. This suggests the use of the smallest abdominal incision compatible with skilful work. The early and free use of the Trendelenburg position in cases where it is not absolutely contraindicated, and tender, skilful, delicate manipulation of the intestines themselves in the separation of adhesions. That we should avoid eventration of the intestines, or their prolonged exposure to the air, goes without saying. But it is probable that in the majority of cases post-operative intestinal obstruction is due directly to adhesions, which form as a result of conditions caused by the operation. This has long been recognized, and many efforts have been made to devise some means by which it can be avoided. Martin has used sterilized olive oil; Morris has used and still uses aristol to cover the denuded surfaces. Other measures have been suggested, but have proved ineffective.

There are several general principles to be kept in mind: (1) That while intestines whose peritoneal epithelium is intact will adhere to raw surfaces, much more quickly and readily will this occur if their peritoneum is abraded. (2) While they will form adhesions to an opposite abraded peritoneal surface, much more readily will they adhere to a raw surface; and (3) that two surfaces denuded of their peritoneum will almost certainly adhere.

What steps can we then take to reduce the formation of adhesions to a minimum? First, as I have remarked, avoid all unnecessary handling of the intestines. This is extremely important, and to this end the aid of posture must be invoked. Every foreign body that touches an intestine robs it correspondingly of its epithelium. It often becomes necessary to wall off the abdominal cavity, or to hold the intestines away by the interposition of gauze sponges or towels. This is an evil that should be absolutely avoided when possible, but when they must be used, let it be with the least possible violence and manipulation. Sänger has urged that, while dry gauze will, without question, remove the epithelial covering of the peritoneum, gauze saturated with a warm soda-salt solution will do much less vio-

lence, and that therefore such solution should be used. Other operators have, after trial, denied this. I believe it to be advantageous. The use of gauze packing to check excessive oozing predisposes to the formation of adhesions. It has been suggested that it might be avoided by the use of steam as advocated by Segeriff to check the bleeding, drainage being secured by the use of a glass tube, instead of gauze.

Again, it is an established principle of abdominal surgery that, where it is possible, raw surfaces should be covered with peritoneum. Much can be done in this line in the treatment of the stump left after removal of an ovary and tube. In a case uncomplicated by adhesions, the appendages can be enucleated according to the method employed by Dr. Pratt of Chicago, with almost no bleeding, and the edges of the peritoneal surfaces of the broad ligament be brought together by a continuous catgut suture, leaving only a linear denudation. Or a chain ligature may be used and the peritoneal surfaces united. A broad, thick stump is undesirable, as neither oil, aristol, nor the cautery will prevent adhesions.

After all serious abdominal operations, especially when complicated by adhesions necessitating more or less violence to the intestines, there is irregular, painful peristalsis during the first twenty-four hours or more. It is then that tonic spasmodic contraction of the intestinal muscles occurs. I have said I believe this occurs oftener than is recognized. In support of this view, let me again mention the two cases reported by Dr. Ashton, where autopsy revealed this condition. Another case was reported to me by Dr. O. E. Herrick, of obstruction following laparotomy, which resisted all measures to provoke a fecal movement, or even the escape of flatus, till finally, in desperation, a quantity of tobacco smoke was thrown into the rectum. In a very short time free fecal evacuations occurred. In my own practice, after a laparotomy for the removal of pus-tubes, efforts to produce catharsis resulted only in the production of nausea and vomiting, which rapidly became fecal. There was only moderate abdominal distension. The pulse and temperature did not indicate sepsis, and yet the most faithful and persistent effort failed to even provoke an escape of flatus. To give the patient temporary relief from the persistent vomiting, I gave a large hypodermic injection of morphin. Within one-half hour her bowels moved *copiously*.

The condition in these cases was, I am confident, tonic obstructive spasm of the intestines, aggravated by injudicious treatment. The indication in such cases is to cause relaxation of the spasm, and thus relieve the obstruction. For this purpose no drug is equal to opium in some form, preferably codein, because of its freedom from nauseating tendencies. In saying this, I am aware that I am advocating that which, in the opinion of many, is heresy. There are those who, in the strongest possible terms, condemn the use of an opiate after abdominal section, but I contend that by the free use of codein during the twenty-four or thirty-six hours immediately following an abdominal operation, the best interests of the patient are conserved. It not only relieves the pain (often severe), but, by its sedative action on the sympathetic nervous system, allays irritation and converts irregular spasmodic intestinal contraction into normal, painless, though active, peristalsis. I always use it freely in this manner, and have never had occasion to regret it. Under its use normal peristalsis, as evidenced by the escape of flatus, is more quickly established, and instead of delaying catharsis, it makes it more easily possible.

The very early use of cathartics in cases of spasmodic abdominal pain after section I cannot sanction. This pain is, as I have said, caused by irregular obstructive intestinal contractions, and the use of a cathartic before normal peristalsis has been restored aggravates the existing irritation. Sedatives are indicated. The condition is parallel to that existing in lead-colic, where no remedy will overcome the existing constipation and promote an evacuation of the bowels as readily or certainly as a free use of opium. Or to those cases cited by Brunton, of obstinate constipation complicating ovarian neuralgia, where opium not only relieved the neuralgia, but produced catharsis.

It may be urged that the use of codein after abdominal section will tend to promote the formation of adhesions by preventing peristalsis, but I cannot think so. The conditions are abnormal. It must be remembered that the intestines are no longer quiet. In addition to the stimulus of irritated nerves, there is the normal stimulus of gas in the intestinal canal. The intestines are no longer empty and flattened as at the beginning of the operation, but by the processes incident to the operation there has been a formation of more or less gas, supplying a normal stimulus to peristalsis within the canal itself. Moreover, the peristalsis is not normal nor regular. It is more or less spasmodic, even obstructive. Codein, properly used, instead of quieting normal peristalsis and allowing adhesions to form, quiets excessive peris-

talsis, regulates the action of the intestines, and renders the production of catharsis possible at an earlier period than by any other means. I believe that in serious abdominal operations the exhibition of cathartics by the stomach should be avoided till it is shown by the escape of flatus that normal peristalsis has been reëstablished, but that we should rely on the free use of codein, supplemented, if necessary, by the use of high enemata.

If, after judicious trial of the measures above detailed the symptoms of obstruction persist, the abdomen should be reopened and the cause of the obstruction sought. Nor should we hesitate to incise the intestines, if necessary, to reduce their volume. For organic obstruction there is no other remedy.

A NEW TREATMENT OF DIPHTHERIA—THE INTRAVENOUS INJECTION OF MERCURIC CHLORID. A THERAPEUTIC SUGGESTION.

BY WALTER L. PYLE, A.M., M.D.,
OF WASHINGTON, D. C.;
FELLOW OF THE AMERICAN ACADEMY OF MEDICINE; FORMERLY RESIDENT PHYSICIAN IN THE EMERGENCY HOSPITAL, WASHINGTON, D. C.; MEMBER OF THE MEDICAL ASSOCIATION OF THE DISTRICT OF COLUMBIA, ETC.

SINCE calling the attention of the English-speaking medical profession, some fifteen months ago, to the superlative merits of the intravenous injection of mercuric chlorid in obstinate cases of organic syphilis, as practised by Professor Guido Baccelli of Rome, it has occurred to me to suggest a new field for this valuable method of medication—its use in the treatment of diphtheria.

Although to my knowledge this suggestion is original and is unsupported by clinical evidence, I feel justified in offering it to those practitioners who, either in their official or private capacities, come in constant contact with diphtheria, and I believe that a careful trial of this method will result in establishing a formidable means of combating this dreaded disease.

My reasons for this suggestion and my belief in its efficacy, despite the absence of clinical proof, which in the last year has all been directed to the serumtherapy, are as follows: (1) *The intravenous injections of mercuric chlorid are absolutely harmless*, and can be practised without pain to the patient. In such a fatal disease as diphtheria any harmless and promising method of treatment is worthy of a trial, particularly if it is not necessary to suspend any other treatment in order that it may be used. There is no reason why any of the local medications now in practice cannot be used in conjunctions with the intravenous injections. Physicians feeling assured of the reliability of the antitoxin serum, need not omit it, but use the intravenous injections conjointly. The advantage will show in the resultant mortality of the series of cases treated. (2) There is greater certainty and rapidity of absorption and therapeutic effect in the intravenous medication than in any other, which in diphtheria, of all diseases, is most necessary. A few hours gained in the treatment of diphtheria will often avert a fatal issue. The system reinforced for the combat with the toxin is less liable to be overcome, and the patient rendered helpless. (3) The therapeutic value of mercuric chlorid in the treatment of diphtheria is universally acknowledged. In addition to its established influence in lessening the plasticity of the blood, and thus diminishing fibrinous exudation, mercuric chlorid has a preservative and tonic influence on the corpuscular elements of the blood, and reinforces them against such a powerful factor of disintegration as the toxin of the Klebs-Loeffler bacillus. (4) Mercuric chlorid is one of the strongest germicides at our command. Distributed directly through the circulation to the points of infection, the maximum degree of germicidal action can be obtained. Germicides applied externally to the infected surfaces rarely reach the bacilli that are imbedded securely in the submucous tissues, and are afforded extra protection by the fibrinous exudation. It is quite possible that the intravenous injections of mercuric chlorid not only combat the disastrous effects of the toxin, but also the bacilli themselves are enfeebled by the extra amount of antisepticized blood that is called forth by the inflammatory changes in the mucous membranes. (5) Experience has proven that the therapeutic value of mercuric chlorid in diphtheria is in direct ratio with the amount of drug employed. By the intravenous injections the maximum influence of the salt can be obtained without untoward salivation or distressing gastric or dermal symptoms. A small dose administered intravenously is more potent than a much larger one given otherwise. Although great tolerance for mercuric chlorid, as well as all other mercurial salts, is shown by diphtheritic patients, yet it often happens that the ordinary administration of mercury is seriously interfered with by the foregoing complications, which sometimes even forbid its further use. (6) In spite of the persistent and meritorious investigation in the therapeusis of diphtheria no remedy is specific, and the limitation of medical science in combating the effects of the Klebs-Loeffler bacillus is a lamented fact. The intravenous injection of mercuric chlorid offers a new addition

to our medical armamentarium. It follows no new theory, it is not a fad, and to me seems substantiated by the simplest and soundest of reasoning.

It is not in the province of this paper to review the advantages of intravenous injection as a method of medication, this I have already done in THE MEDICAL NEWS of February 23, 1895, (a comprehensive epitome of which can be found in the *British Medical Journal* of August 17, 1895). The *safety* of the method and its efficacy in the treatment of syphilis has been firmly established by the Italian school, and the interested reader is referred to my paper, or to the originals in Italian of Baccelli,[1] Jemma,[2] Dagnino,[3] Colombini,[4] and Nieddu.[5] DeVecchi, now in San Francisco, has followed his *confrères* in an exhaustive exposition of this method, and Blaschko[6] has reviewed it in Germany, calling especial attention to the small amount of the drug that will prove efficient, when given in such a way that all the dose becomes effective.

For the convenience of those who are unfamiliar with the technic of the method I will quote briefly from my former article:[7]

"In the preparation of the fluid for injection the following formula is used:

℞	Mercuric chlorid . . .	1 grm.
	Sodium chlorid . . .	3 grms.
	Water . . .	1000 grms.

A small quantity of alcohol may be added to facilitate solution. The mixture should be well stirred and filtered until perfectly clear. It is advisable, but not necessary, to sterilize it, both to be perfectly aseptic and to facilitate solution.

A ligature is applied above the elbow, and any one of the superficial veins in the neighborhood, which soon become prominent, may be selected as the point of injection. The point selected and the surrounding area are then thoroughly scrubbed and disinfected with a $\frac{1}{1000}$ solution of mercuric chlorid or a five per cent. solution of carbolic acid. The needle, previously sterilized, is plunged directly toward the center, at the point selected, and a few drops of blood allowed to ooze out, assuring entrance into the vein; the barrel is then carefully applied, avoiding any entrance of air.[8]

Loosen the ligature and make the injection, at first using only one gram of the solution, and progressively increasing to as high as four grams at a dose if necessary. Occasionally on the withdrawal of the needle there is some extravasation of blood into the neighboring subcutaneous tissue; but this is absorbed very quickly, and is only of casual occurrence. Repeated injections can be made in the same vein. Jemma reported a case in which he made seventy-five injections into the median cephalic vein. This vein and the median basilic are the best to use.

There are two precautions that should be remembered: First, always use a fresh solution, which the physician should prepare himself, to be assured that the salt has not decomposed, which is often the case after the solution has been standing some time. No after-dressing is needed, and it is not necessary to cover the wound of puncture with collodion. Second, do not use a concentrated solution. That of $\frac{1}{1000}$ is to be prepared, but in late injections a $\frac{1}{500}$ solution may be used."[1]

In young children it would perhaps be advisable to start with less than one gram of the solution (.001 gram of the salt), one-half gram of the solution would be sufficient for the first injection, and then increase to 1, 1½, and 2 grams.

Intravenous medication is in its infancy, and it seems possible that this means of administering drugs, with its many advantages, will be universally used when a speedy and maximum effect is desirable. It offers a comparatively unexplored field for experimentation.

THE SIGNIFICANCE OF MURMURS IN THE DIAGNOSIS OF VALVULAR DISEASE OF THE HEART.[2]

BY ALOYSIUS O. J. KELLY, A.M., M.D.,
OF PHILADELPHIA;
VISITING PHYSICIAN TO ST. MARY'S HOSPITAL; PATHOLOGIST AND CLINICAL ASSISTANT TO THE NEUROLOGICAL DEPARTMENT OF THE PHILADELPHIA POLYCLINIC; PATHOLOGIST TO ST. AGNES' HOSPITAL; ASSISTANT TO THE MEDICAL DISPENSARY AT THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

AN acquaintance with the facts renders patent to the observer the avidity with which many practitioners are prone to regard as pathognomonic a sign or symptom of value, though it be yet far from possessing the dignity and importance which they attach to it. Pathognomonic signs are rare, extremely rare; they rarely ever exist. A profound acquaintance with the exact relationship existing between pathological processes and signs and symptoms of disease is the *sine qua non* of accurate diagnosis. I know of no circumstances under which a lack of appreciation of this neces-

[1] I will be glad to furnish literature on this subject to physicians not having the references quoted at their disposal.
[2] Read at the meeting of the Medical Society of the State of Pennsylvania, Harrisburg, May 19–21, 1896.

sity, from ignorance or other causes, is attended by such frequent and needless diagnostic errors, as in estimating the significance of murmurs in the diagnosis of valvular disease of the heart. We are often told that a patient with an adventitious sound heard at the apex of his heart or thereabout has a mitral murmur, and forthwith we are expected to believe that he has some disease of his mitral valves, which on the autopsy table is, but too frequently, found to have "vanished into the thin air."

The study of the exact significance of murmurs in the diagnosis of valvular disease of the heart may not inappropriately be prosecuted by arranging our cardiac cases into three distinct classes: (1) Cases in which the presence of a murmur assists in the diagnosis of some valvular lesion; (2) cases in which, despite the presence of a murmur, valvular disease may not be diagnosed; (3) cases in which valvular disease may be diagnosed without the detection of any murmur whatever. In the present communication these classes can be but alluded to. Nor can we go fully into the question of the diagnosis of valvular disease of the heart. We can do no more than merely indicate the value of other diagnostic signs, directing our attention at present solely to murmurs.

It is in cases belonging to the first two categories, cases in which we may detect a murmur in the region of the heart, that most mistakes are liable to occur, especially in view of the much greater frequency of these classes of cases. In pursuance whereof, it may therefore be remarked as the actuating motive of this communication, that a murmur alone, that is, without corroborative evidence is never diagnostic of any valvular disease of the heart. Disease at any orifice of the heart so disarranges the mechanism of a rhythmically acting and perfectly regulated machine as to of necessity always lead to consecutive changes, without the detection of which, the diagnosis of such valvular disease is never justified.

The first requisite absolutely essential to the accurate diagnosis of valvular or other disease of the heart is a thorough physical examination of the lungs and pleura. We must first determine whether or not there be present any acute or chronic, local or general, disease of the lungs or pleura. For the varying states of health and disease, to which the lungs and pleura are subject, find an expression to a certain, often marked, degree in the condition of the heart; which condition is very frequently similar to that which follows in the wake of certain valvular lesions. The truth of this statement is apparent when we consider that the accentuation of the second pulmonic sound which plays such an important rôle in the diagnosis of certain valvular lesions of the left side of the heart, is also present in cases of pneumonia, as well as in cases of pleural effusion, and the more chronic affections, such as emphysema, etc.

Considering then the question of murmurs, a murmur heard in the region of the heart must be first definitely determined to be of endocardial origin. We must eliminate all questions of exocardial genesis, all pericardial, cardio-pulmonary, so-called hemic and venous murmurs. It will be neither appropriate nor opportune to here enter upon this subject in detail. We recognize then that a murmur heard in the region of the heart may be due to incompetency of the valves or to stenosis of the orifices consequent upon endocarditis or atheroma; to dilatation of the ventricle or relaxation of its walls, inducing a relative insufficiency of the valves; to irregular action of the heart; to roughening of the pericardial surfaces (pericarditis, pleuritis); to anurism; to alteration in the constituents of the blood, anemia and chlorosis; to murmurs produced within the veins; to various anomalous conditions of the chordæ tendineæ; and to various congenital defects of the heart itself or great vessels.

We will consider somewhat in detail the most commonly occurring murmurs, without regard to the accuracy of the diagnosis of the murmur as such. I wish not only to refer to the positive signs of valvular disease but I desire also to direct some attention to the value of what may be termed the negative signs of the individual lesions. And firstly, the systolic murmur with its area of maximum intensity in the region of the apex beat, usually designated the mitral systolic murmur, and which, when detected, is usually considered sufficient evidence to consign the patient to the inconveniences and consequences of a mitral insufficiency, and which when absent usually presupposes the non-existence of such lesion. And yet how frequently is the hemic murmur of chlorosis and the other anemias heard loudest at the apex and during the systole? And how many pericardial, and cardio-pulmonary or pleuro-pericardial murmurs have their point of maximum intensity at, or are heard only in the same region, and are audible, or thought to be audible, only during systole? And on the other hand, how frequently is the murmur of mitral insufficiency not heard with maximum intensity in the region of the apex, but upward toward the

pulmonary cartilage where we usually hear loudest the so-called hemic, or accidental, or functional murmurs? The importance of a correct diagnosis is further emphasized by the fact of the frequent occurrence of these accident murmurs in apparently healthy individuals. They are usually demonstrable in most delicate women, especially in those who have thin chest-walls, and are of very frequent occurrence in young children, more particularly in those who, for any reason, are somewhat below par.

They are especially audible in the recumbent posture. This is also frequently true of the organic murmur of mitral incompetency, which may even be entirely absent at certain times, as during intercurrent diseases and in conditions of weakness and exhaustion. The diagnosis of a mitral insufficiency is justified only, when in addition to a mitral systolic murmur there are present the confirmatory evidences of the consecutive changes which such a lesion necessarily induces in the heart. We must determine the characters of the heart sounds at the apex and at the base (accentuation or not), the character of the apex beat, the area of the cardiac dulness, the condition of the precordium, the presence or absence of a thrill.

Illustrating the care essential in making a correct diagnosis, I may cite the case of a young woman suffering from an attack, which was the second, of acute articular rheumatism, when I first saw her. In conjunction with other physicians I saw her almost daily for a couple of months and carefully watched the sequence of events. During the attack of rheumatism her heart remained absolutely unaffected. As defervescence was established and convalescence begun she became very anemic. There developed a blowing systolic murmur heard loudly at the apex, but apparently with its point of maximum intensity up toward the pulmonary cartilage. There occurred some slight increase in the transverse area of the cardiac dulness. Otherwise physical examination of the heart revealed nothing abnormal. In this instance the natural inference most probable to many would have been the development of a mitral insufficiency due to endocarditis, attendant upon an attack of acute articular rheumatism. While there existed many reasons in support of such a diagnosis, weighty elements in confirmation were wanting, and there existed many negations. For the supposition of a mitral insufficiency there were the history of rheumatism, a systolic murmur heard loudest in a region where the systolic murmur of mitral insufficiency is sometimes located, and some increase in the transverse area of the cardiac dulness. But the patient had a marked anemia, the murmur was of the character and located where the hemic murmurs are most frequently heard, there was no accentuation of the second pulmonic sound, the first sound at the apex was preserved, and the slight increase in the transverse area of the cardiac dulness could readily be explained upon the assumption of a slight dilatation of the heart dependent upon the anemia. While the case might well be thought doubtful, this latter supposition was indulged in and subsequent events proved its justification. As the anemia improved so also did the physical signs of the heart; the murmur disappeared and the area of cardiac dulness once more assumed its normal limitations. The patient was seen again some months after she left the hospital, and there existed no physical signs or indications whatever of cardiac disease; the heart sounds were normal, there was no murmur, no accentuation of the pulmonic second sound, no increase in the area of cardiac dulness, no change in the precordium, no alteration in the pulse; her anemia was gone, so also were all her suspicious signs of valvular disease. The case was not one of relative mitral insufficiency, as whether relative or due to endocarditis, the physical signs of a valvular lesion, upon which the diagnosis is to be based, are the same.

A stenosis of the mitral orifice is usually diagnosed, and only then, when there is detected a diastolic or a presystolic murmur with its area of maximum intensity at the apex. This diastolic or presystolic murmur is usually said to be strictly localized at the apex, to indicate the fallacy of which statement I need but refer to the very old testimony of Bamberger,[1] or to the more recent communication of J. P. Crozer Griffith.[2] The latter diagrammatically illustrates the very wide area of distribution of many presystolic and diastolic murmurs of mitral stenosis. Of all cardiac murmurs the presystolic at the apex is usually said to be the one pathognomonic; being a positive indication of mitral stenosis. This statement is equally as fallacious as the preceding one, regarding its limitations of distribution. For many years, since Austin Flint first promulgated the statement, we have been accustomed to occasionally hearing a presystolic murmur at the apex in cases of aortic incompetency, and such a murmur has usually gone by his name. More recently Fischer[3] and Phear[4] have contributed to the lit-

[1] "Lehrbuch der Krankheiten des Herzens," 1857, p. 248.
[2] *American Journal of the Medical Sciences*, September, 1895.
[3] *Lancet*, March 5, 1895.
[4] *Lancet*, September 21, 1895.

erature of the subject, the latter collecting 48 cases of presystolic apex murmur without mitral stenosis. In 17 of these cases the aortic valves were incompetent, in 20, the pericardium was adherent, and in 13 there was present either a presystolic or a diastolic thrill. It has long been known that there may occur at the apex a presystolic or a diastolic thrill without any murmur being audible, the thrill in such cases being considered pathognomonic of the mitral stenosis. But from the evidence adduced by Phear this can no longer be considered consistent with the facts. A presystolic murmur at the apex may therefore not only be due to a mitral stenosis, but may likewise owe its origin to an aortic incompetency or to an adherent pericardium. It has also been suggested that in certain rare instances, either one or two conditions, shortening of the chordæ tendineæ, or dilatation of the left ventricle, with in either case the necessary addition of a sufficiently forcible contraction of the left auricle, may serve to produce the murmur. The condition of the chordæ tendineæ was mentioned in 9 of the cases referred to by Phear. In 3 they were healthy; in 2 shortened; in 1 shortened and thickened; in 3 thickened but not shortened. In one of the last mentioned cases there was also an adherent pericardium. It has also been suggested that in those rarer instances of presystolic apex murmur attendant upon aortic incompetency or adherent pericardium, the innervation of the heart may be in some obscure way affected, giving rise to the production of the murmur.

And further a mitral stenosis is frequently to be diagnosticated without the detection of any murmur whatever. One can at least think of the presence of a mitral stenosis when a well-marked hypertrophy of the right side of the heart and accentuation of the second pulmonic sound cannot be accounted for by any existing conditions of the lungs, and when for the accompanying weakness and smallness of the pulse no plausible explanation can be found. The presystolic murmur of mitral stenosis may be absent for months at a time, and is especially liable to be found wanting toward the close of life when cardiac weakness begins to manifest itself. Requisite for the production of the murmur is a certain strength of the left auricular contraction, which with the increasing exhaustion toward the end of life necessarily suffers.

The unwary are thus often surprised to find *post-mortem* a mitral stenosis unsuspected during life.

Again, there is another class of cases in which we can detect no presystolic or diastolic murmur, and in which the diagnosis of mitral stenosis can be made with absolute certainity. I refer to cases in which there is a reduplication of the second sound heard at the apex alone, or at least at the apex with greatest intensity. Reduplication, or splitting of the second sound, at the base of the heart is devoid of much diagnostic significance. But a reduplication of the second sound heard only at the apex, there being no such reduplication audible at the base, is diagnostic of mitral stenosis. This so-called reduplication of the second sound, which in fact occurs in quite a number of the cases of mitral stenosis, is in reality not a reduplication or splitting of the normal second sound of the heart, but is the addition of a distinct and independently produced third sound, an abnormal diastolic or presystolic tone. It is produced by the auricular contraction causing a sudden and violent presystolic impact of the blood against the pathologically tense and non-retracting mitral valves. Unless the valves have become too stiff to permit of the production of any sound at all, this abnormal sound is frequently very readily heard if it be not obscured by a co-existing or replacing murmur. This triple rhythm of the cardiac sounds may often be the only auscultatory signs of mitral stenosis. It is most frequently observed during quiet cardiac action, to be usually replaced, during excited action, by the normal double rhythm of the cardiac sounds, and a diastolic or presystolic murmur.

Particularly are we to exercise care in the diagnosis of single lesions at the mitral orifice; they are of rather infrequent occurrence. Stenosis of the mitral orifice is almost always accompanied by incompetency of the mitral valves, while the majority of cases of mitral insufficiency are attended by some degree of stenosis of the orifice. The valvular incompetency is usually the antecedent affection, the stenosis developing subsequently. We must be careful not to mistake a stenosis for an insufficiency, or a double lesion for a single one. Frequently the stenotic murmur failing, we have present only the systolic murmur of the coexisting mitral insufficiency. We must have recourse to the other physical signs in addition to the murmur. The preponderating lesion can be diagnosticated by attention to the physical signs of the individual lesions which in the single case may be more in evidence.

The murmurs produced at the aortic orifice, and usually heard with maximum intensity at or near the aortic cartilage, are the aortic systolic and aortic diastolic murmurs; and I know of no

signs, in the proper interpretation of which more errors are made than in correlating these two murmurs to the pathological conditions which give rise to them. The murmur of aortic incompetency is diastolic in time, in pursuance whereof to many, all diastolic murmurs heard with maximum intensity in the region of the aortic cartilage of necessity indicate, and the murmur alone is sufficient to diagnosticate, an aortic insufficiency. In addition to giving rise to an aortic diastolic murmur an aortic incompetency will surely be productive of other evidences of deranged cardiac mechanism without the demonstration of which the diagnosis of an aortic insufficiency is never justifiable.

We must have recourse to the other signs of the valvular lesion, and consider the character of the heart sounds at the apex and at the base, determine the area of cardiac dulness, the characteristics of the apex beat, the presence or absence of a thrill, the condition of the precordium, the pulse, the results of auscultation of the arteries, etc.

It may be asserted that an aortic diastolic murmur will so surely be accompanied by other evidences of aortic incompetency as, for diagnostic purposes, to render almost needless such careful examination; in other words. that an aortic diastolic murmur is pathognomonic of aortic insufficiency. And I will even grant that in the majority of cases this may be true, but it is not invariably so. The hemic murmur at the base of the heart, being systolic in time, will of course not be mistaken for that of aortic insufficiency. But there are other signs attendant upon anemia which may lead to confusion. I refer to the bruit in the veins. This so-called "bruit de diable" has long been known to be audible in the jugular veins, and can occasionally be heard in other veins. It is a continuous murmur, and as such it is usually appreciated. It suffers systolic and diastolic augmentations, although the latter, because of the much easier flow of the blood during that time of the cardiac cycle, is much the more intense. This murmur is not only audible in the veins of the neck, but can very frequently be heard along the right border of the sternum as far down as the second or third rib, exceptionally still lower. When heard, however, in this region, that is at the base of the heart, it usually appears simply as a diastolic murmur. Under these circumstances, attaching itself, so to speak, to the second sound of the heart, it may readily be mistaken for the diastolic murmur of aortic insufficiency. Exceptionally this murmur may be heard with great intensity low down the sternum, in which case it is probably transmitted from the inferior vena cava. This venous murmur is occasionally present in apparently healthy individuals, but is most frequently observed in those the subjects of anemia, especially chlorosis. It is of very frequent occurrence in children, as has been especially pointed out lately by Sainsbury,[1] who found it present in thirty-four of one hundred children whom he examined. These children, while possibly somewhat below par, were none the subject of any disease. The diagnosis of anemia, the cessation or diminution in intensity of the murmur upon deep pressure on the jugular (light pressure may serve to increase it), and the absence of corroborative evidences of aortic insufficiency serve to protect from diagnostic errors. Ausculting from the base of the heart toward the jugular vein one can satisfy oneself that this diastolic murmur gradually merges into a rhythmic diastolic augmentation of the continuous venous hum of the jugular. Otherwise the occurrence of an inorganic diastolic murmur is practically unknown, and the detection of such a murmur argues with the greatest probability in favor of an organic lesion.

But again, an aortic incompetency very frequently exists without there being present any diastolic murmur capable of detection. Especially is this true of the greater degrees of incompetency. Under such circumstances we have recourse to the other signs of aortic insufficiency, and the character of the pulse is such a positive indication of the condition as to often almost permit us to make the diagnosis from it alone. And it is precisely in such cases that errors are liable to occur. Between eighty and ninety per cent. of all cases of aortic incompetency are accompanied by an aortic systolic murmur without there being present any stenosis of the orifice whatever. In other words, a systolic murmur at the aortic cartilage does not indicate stenosis of the aortic orifice; such a condition being among the rarest of cardiac valvular lesions. But frequently in aortic incompetency the only murmur audible is an aortic systolic one, the second sound being absent, or almost so; or it may be feebly preserved. Under such circumstances, there being present the other physical signs of an aortic insufficiency, such an aortic systolic murmur may be made use of to supplement the diagnosis of an aortic incompetency. The genesis of this aortic systolic murmer, there being absolutely no stenosis of the aortic orifice present, has been explained upon the supposition of: (1) A great increase in the rapidity

[1] *Lancet*, February 29, 1896.

of the expulsion of an excessive quantity of blood, and a consequent excessive distension of the aorta during the ventricular systole, whereby ensue irregular movements of the walls of the aorta, which are causative of the murmur; (2) a sudden and violent meeting of the systolic stream of blood with the regurgitating stream; (3) roughness and irregularities of the aortic valves, dependent upon endocarditis or atheroma, and against which the blood impinges during systole.

An aortic stenosis is, however, characterized by the occurrence of a systolic murmur transmitted into the carotids, but with its point of maximum intensity at the aortic cartilage. The murmur alone, however, is not diagnostic of the lesion. I do not need to again review in detail the various conditions to which a systolic murmur at the base of the heart may owe its origin. The justification of the diagnosis of a stenosis of the aortic orifice is found in the demonstration of the physical signs of the physical conditions dependent upon the lesion. And particularly must I mention the "*pulsus tardus.*" We also take into consideration the other physical evidences of the lesion, not forgetting the importance of negative signs, or signs indicative of another lesion. We must bear in mind that we very frequently also hear an aortic diastolic murmur dependent upon an aortic insufficiency, with which, in fact, the majority of cases of aortic stenosis are complicated.

Of not less importance, in considering lesions at the aortic orifice, is determining the presence or absence of an aortic aneurism, which, if present, may give rise to a systolic, a diastolic, or a double murmur. But the signs and symptoms pertaining to anurism on the one hand, and to aortic disease on the other, guard against error. Of course, aortic disease and an anurism may coexist.

While by reason of their much less frequency of occurrence, valvular lesions of the right side of the heart are less liable to lead to diagnostic errors than are those of the left, still, as they do occur, it behooves us to make no mistakes. Clinically, the most important right sided lesion is a tricuspid insufficiency, which is usually relative, and secondary to some disease of the left side of the heart, most frequently at the mitral orifice.

And once again, a murmur-systolic, at the lower end of the sterum, is not diagnostic of the condition. It is usually difficult to distinguish this murmur from one produced at the mitral orifice, and which frequently accompanies it. We have more regard for the area of cardiac dulness, the non-accentuation of the previously accentuated second pulmonic sound, the result of an examination of the veins, etc. The veins show pulsations, presystolic-systolic in time, especially affecting the jugular, though they may occur in other veins, and are frequently demonstrable in the liver. These venous phenomena have elsewhere been the subject of a more detailed dissertation.[1]

We bring similar aids to assist us in the diagnosis of that much rarer and usually congenital lesion at the tricuspid orifice, stenosis. This lesion is, however, comparatively speaking of such rarity, and almost never exists without an accompanying insufficiency of the tricuspid valves, that its diagnosis is a matter of little practical moment. A diastolic or presystolic murmur would be of value in the diagnosis, as also would an examination of the veins, etc.

The lesions at the pulmonary orifice, almost without exception congenital, present physical signs the counterpart of those which accompany similar lesions at the aortic orifice. Stenosis of the pulmonary opening is of more frequent occurrence than incompetency of the pulmonary valves. It is, however, hoped that at this day no one will mistake the accidental hemic murmur, or the murmur of mitral insufficiency at times heard at the pulmonary cartilage, for an indication of pulmonary stenosis.

Of necessity, because of the complexity of the conditions, it is in cases of combined valvular lesions that more difficulty will be experienced in making the correct diagnosis. But in such cases similarly as in cases of single lesions, the diagnosis is to be based upon the demonstration of the physical signs of the pathologically changed physical condition of the heart. Of those signs the murmur, or murmurs, present, constitute a part. The detection of a murmur and the localization of it to its seat of origin, are essential elements in the diagnosis, but alone they do not justify the diagnosis. It is true that in very few conditions, save those of valvular lesions, do we meet with multiple murmurs, but it is equally true that conditions which give rise to the production of single exocardial murmurs may exist in combination. The systolic hemic murmur of anemia at the base, and the diastolic murmur transmitted from the veins may be confused with the murmur of double aortic disease. Disease of the mitral or aortic valves may coexist with pericarditis. In estimating the probability of multiple lesions we must always take into consideration the preponderance of signs suggestive

[1] *New York Medical Journal*, January 18 and 25, 1896.

of individual lesions, as the signs of one lesion are necessarily modified by the development or presence of another. Illustrative thereof I may cite the

Case of a man, aged about twenty-eight years. He had a bulging precordium, a heaving cardiac impulse, a diffuse apex beat with maximum intensity in the sixth interspace, one inch outside of the mammillary line, a presystolic thrill at the apex, great increase in the area of the cardiac dulness transversely (to the right and left), and in the direction of the long axis of the heart. On auscultation at the apex, in addition to a fairly well preserved, rather valvular-like first sound, there was a systolic murmur and a reduplication of the second sound. At the aortic cartilage, there was a systolic murmur quite different in character from that heard at the apex; the second pulmonic sound was accentuated, but at the base there was no reduplication of the second sound. The pulse, while not excessive in volume, was distinctly the *pulsus celer et altus*, the Corrigan pulse. The diagnosis was made of mitral insufficiency and stenosis and aortic insufficiency. The area of cardiac dulness indicated hypertrophy and dilatation of both sides of the heart, aortic and mitral disease. The mitral insufficiency was further indicated by the systolic murmur, the mitral stenosis by the valvular rather accentuated first sound at the apex (the other lesions should have diminished its intensity), the reduplicated second sound at the apex, and the presystolic thrill, the presence of both lesions being further confirmed by the accentuated second pulmonic sound. The aortic incompetency was indicated by the area of cardiac dulness, the character of the apex beat, and the Corrigan pulse, somewhat modified in character by the concomitant mitral disease. The systolic murmur at the aortic cartilage indicated simply disease at the aortic orifice, and not stenosis, as there was no corroborative evidence of such a lesion. The necropsy confirmed the diagnosis.

Multiplication of instances is useless.

As we are at present dealing not so much with the diagnosis of valvular lesions as with the significance of murmurs in their diagnosis, we cannot consider more in detail these interesting conditions, nor can we take up at all the study of various anomalous states inducing murmurs, such as patulous foramen ovale, defect of the interventricular septum, persistence of the ductus arteriosus, or various anomalous and pathological conditions of the chordæ tendineæ, or intraventricular bands. These latter may sometimes produce systolic murmurs, simulating mitral incompetency.

It will be noticed that I have not qualified the murmurs except by the time of their occurrence. It is not the character of a murmur, nor its area of distribution or propogation, nor its direction of transmission that determines it value in the diagnosis of valvular disease of the heart. All of these are subordinate to the time of its occurrence and the site of its production.

There is a certain analogy existing between the significance of murmurs in the diagnosis of valvular disease of the heart, and the detection of albumin in the urine in the diagnosis of nephritis. As murmurs are usually present in cases of cardiac valvular disease, so also is albumin present in the urine in the event of nephritis, but neither is pathognomonic of the condition which they attend; they both require confirmatory evidence. The analogy can be carried still further. As some cases of valvular disease may be diagnosticated without the detection of a murmur, so may we also diagnosticate nephritis in certain rather unusual instances when we fail to detect any albumin in the urine. In some interstitial cirrhotic conditions of the kidney, the specific gravity, the daily quantity of the urine, casts, etc., and the consecutive changes in the heart and circulatory apparatus are sufficient evidence upon which to base the diagnosis of nephritis although albumin be absent from the urine.

I have attempted while endeavoring not to underestimate the value of murmurs in the diagnosis of valvular disease of the heart, to suggest that they are often overestimated, and to point out that they are never of pathognomonic significance. I have endeavored to draw more attention than is usually accorded to the other and important physical signs of valvular disease of the heart. It is the other physical evidences of the necessary changes consecutive to the valvular defect that form the justification of the diagnosis. The murmur is but one element in the diagnosis, and I would almost say the least important.

CLINICAL MEMORANDA.

CASE OF TRAUMATIC TETANUS SUCCESSFULLY TREATED WITH VERATRUM VIRIDE AND GELSEMIUM.

By FORDYCE GRINNELL, M.D.,
of Pasadena, Cal.

Guy B., a boy, aged six, while playing in his yard, barefoot, cut the ball of his left foot on a piece of glass. The wound apparently healed. Some nine days after (April 14th), he complained of stiff jaws and difficulty in swallowing. These symptoms increased until, on the night of the 16th, tetanic spasms began to manifest themselves. The cicatrix of the wound was cleaned and scraped. It seemed somewhat tender on pressure, but no foreign body was discovered. The site was scarified,

however, and turpentine and oil applied, and four-grain doses of ammonium bromid were given every two hours.

As no perceptible improvement was noted, on the 17th Norwood's tincture of veratrum viride was given, at first one drop every hour, then two drops every hour. As this did not seem to prevent the return of the spasms from time to time, fluid extract of gelsemium was given, at first in drop doses every hour, in conjunction with the veratrum, then in two-drop doses, and finally in three-drop doses. The veratrum was also increased on the 20th to three drops every hour, so that the child was taking three drops each of the veratrum viride and the gelsemium every hour, and it seemed to require this amount to control the spasms. This dosage was continued for forty-eight hours. Only once during this time did it produce active vomiting, or sufficient nausea to require an opiate to control it. When this relaxed condition was obtained, the drops were decreased to two of each on the 22d, and on the 25th to one of each, which was continued until the 27th, when the interval was lengthened to two hours, and gradually thereafter discontinued.

The ammonium bromid was given in three- to four-grain doses every two hours during this entire period.

The remedies in diminished doses were continued to the 30th of April, when the boy could open his mouth without difficulty, had a good appetite, was playful, but more boisterous in his manner than usual, or, as his mother said, "more nervous."

The remarkable thing to me was the tolerance in one so young of such powerful remedies and in such doses. It seemed to require these doses to control the conditions producing the tetanic spasms. The instructions were to decrease the amount and frequency of dose when distinct signs of nausea appeared or the signs of convulsions abated.

I had been led to think that veratrum viride might prove a valuable remedy in traumatic tetanus, as it had done in puerperal and other convulsions, and that gelsemium, in its peculiar action in causing relaxation of the muscles of the jaw, might prove a valuable adjunct, and in this case these remedies did not disappoint.

COMPOUND FRACTURES.[1]

BY W. T. DODGE, M.D.,
OF BIG RAPIDS, MICH.;
SURGEON TO MERCY HOSPITAL.

THE tendency has been manifested during the past few years among many of our friends who are connected with railroads to report all classes of injuries received on the rail under the general heading of "Railroad Surgery." While I have never been connected in any capacity with a railroad, I have nevertheless had much experience during the last six years in this branch of surgery. During that time more than seven hundred cases of injury have been admitted into Mercy Hospital at Big Rapids, and with the treatment of all of them I have had more or less to do. While these cases of injury have ranged all the way from insignificant bruises to severe crushing of the limbs and trunk resulting in death a few hours after admission, the majority have been cases of bruising or crushing of the legs with or without broken bones of all grades of severity. These injuries have been caused generally by the limbs having been caught between two logs, or in some accident on one of the various logging railways of Northern Michigan. I have been unable to recognize any difference in the pathological conditions in a leg crushed between two logs and one crushed between two car-couplers, and I think the term "Railroad Surgery" is not properly applied to this class of injury.

A compound fracture may vary in severity from a small puncture in the skin leading down to an ordinary fracture to a severe crushing of the soft parts with much comminution of the bones. In the less severe injuries the indications for treatment are very plain, and at the present day are usually well carried out by all practitioners. They are to clean the injured limb in the surgical sense, apply dressings that will seal the wound, and keep the bones in proper position and at rest. Careful watch should be kept of the case, and if, in spite of the aseptic precautions, suppuration ensues, free incisions should at once be made, and antiseptic measures adopted. It is in the more severe class of injuries, however, that the surgeon's judgment is put to the test, and if he attempts to save the limb the patience and perseverance will be severely tried. When called to attend a broken limb associated with extensive crushing and laceration of the soft parts, the first question to decide is whether an amputation shall be done at once, or whether an attempt will be made to save the injured member. I believe that in nearly all cases except in those in which the tissues are ground to a pulp, amputation should not be immediately performed, but that the patient should be given the benefit of delay. In the apparently hopeless cases the injured limb and surroundings should be cleaned as thoroughly as possible without increasing the traumatism, surrounded with warm antiseptic dressings, and kept at rest without attempting to place the broken bones in apposition until the inflammatory reaction following the injury has subsided. Should general gangrene of the limb ensue amputation should be performed, but if the gangrenous process is localized I should not consider it an indication for amputation even if considerable tissue is destroyed and extensive necrosis of the bone occurs. Patience, perseverance, and a thorough, painstaking application of the principles of antiseptic surgery may result in saving the limb. As soon as the inflammatory reaction has subsided the dead tissue should be removed, necrosed ends of the bones sawed off, the limb brought into a good position and maintained there in a swing, or by means of any simple retention apparatus that will permit the use of gauze dressings and irrigation of the limb.

The celebrated case of Dr. Donald Maclean reported by him in a paper read before the Ohio State Medical Society in 1894, and in this Society by Dr. Tibbals last year, is one of the most wonderful cases on record in this class of injuries. The report of that case inspired me to successfully attempt the saving of limbs that before I should have amputated, and has also induced me to again call your attention to this important subject.

[1] Read before the Michigan State Medical Society, June 4, 1896.

Without further preliminary I will now submit the report of a few cases that will illustrate the method of treatment advocated.

CASE I.—J. M., a Swede, who was admitted to Mercy Hospital, June 22, 1892, had had both legs fractured below knees the day before in an accident on the railway. The right leg sustained a simple fracture, which united in a short time. The left one, however, was caught between two logs and severely bruised, the skin being broken over a fracture at the middle third. We thoroughly cleaned the leg, placed the bones in apposition, and sutured the soft parts which healed by first intention. At the end of a month there was non-union of the tibia. A plaster dressing was then applied and the patient encouraged to move around, but after several weeks the bones were still ununited. An incision was then made over the point of fracture which was found to be very oblique, extending three inches in length of the shaft of the bone. Much fibrous tissue separating the fragments was removed and the bones fastened together with bone nails. A plaster dressing was applied and allowed to remain one week. During this time the patient felt well, had a good appetite, slept well nights, and was free from pain and fever. These favorable symptoms were considered conclusive evidence that all was well at the seat of the operation. Nevertheless, at the end of one week the patient had a severe rigor, whereupon the splint was removed and the wound found to be full of pus, and the entire leg and foot the seat of a violent erysipelatous inflammation. Free incisions were made and the disease in the leg soon brought under control, so much so that the fractured bones united without further difficulty. Not so with the foot. Necrosis of the tarsal bones supervened, necessitating several operations for the removal of dead bone. Eventually, after eight months' treatment the foot became sound and the patient began walking around with the assistance of a cane. He continued doing this several weeks when suppuration again occurred in the foot and rapid destruction of the bone ensued. By this time the patience of all concerned had been exhausted, the patient was very anxious to return to Sweden and begged for amputation. The confidence of the doctors in the powers of Nature to restore the lost bone was shaken, and the foot was amputated at a point about three inches above the ankle below the original fracture of the tibia. The stump healed kindly.

CASE II.—O. M. was admitted to the Hospital January 6, 1893, his leg having been caught between two logs, the soft parts badly crushed and lacerated, and a compound, comminuted fracture of the tibia and fibula sustained. We removed the loose fragments of bone, cleaned and crushed tissues thoroughly, and placed the broken bones in apposition. Suppuration supervened in a few days, and the patient decided to have the leg amputated, after the chances of saving it had been duly presented. This was accordingly done, and he was discharged February 20th. A little more courage on the part of the patient, and perseverance on the part of the surgeons would probably have preserved this leg.

CASE III.—L. O., a Swede, was admitted to Mercy Hospital, October 26, 1894. Eight weeks previous a compound fracture of the right leg had been sustained, and the soft parts had been much bruised and lacerated. The skin had been destroyed over a considerable area, and there were two granulating patches about the size of silver dollars when he was admitted to the Hospital. The deep tissues had healed, however, and the bone appeared to be partially united, only a slight degree of mobility being present. I encouraged the patient to walk, thinking that exercise would stimulate union. Instead the mobility increased and soon a loose fragment of bone could be detected on the anterior surface of the leg, which slipped out easily through a small incision. We then irritated the fractured tibia by driving a drill several times into the fragments and rubbing the ends together, although they were so firmly attached to each other as to permit but limited movement. The position of the limb being good and partial union having apparently occurred, the small incision was closed and the leg placed in plaster-of-Paris. The wound healed by first intention, but in four weeks the bone was found more movable than before, and the position of the fragments not so good. A free incision was then made over the broken bone, when it was discovered that the fracture had been an impacted one. The sharp posterior point of the lower fragment had been forced upward under the periosteum of the upper fragment, the detached piece previously removed having filled up the depression in the anterior surface of the limb very nicely, and thus conveyed the impression that the bones were in perfect apposition. So firmly were the fragments impacted that we found it impossible to separate them until the end of the lower fragment had been divided with the chain saw. The bones were then brought into apposition and wired. The skin was carefully sewed and antiseptic dressings applied. We had been having trouble with erysipelas in the Hospital about that time, and, although a thorough cleaning had been gone through with immediately before this operation, in a few days the patient's entire leg became the seat of a violent erysipelatous inflammation. The suppuration thus produced gave us work for many months, necessitating on two occasions the removal of dead bone from the leg. Eventually the necrotic process was arrested and the bone became firmly united. He was discharged about six months after admission.

CASE IV.—W. P. This patient had his left foot caught between two car-couplers September 1, 1894, and Dr. W. A. Kuhn of White Cloud, Mich., found the foot crushed and the lower third of the leg severely bruised, but could detect no broken bones and therefore concluded to attempt to save the leg. He made use of warm antiseptic applications but failed to restore the vitality of the injured member, and called me in consultation nine days after the injury. I found the foot gangrenous and the lower third of the leg much discolored, in fact, the discoloration extended nearly to the knee. There was, of course, nothing to do but amputate. The tissues were edematous and discolored nearly to the knee, but a line of demarcation had formed just above the ankle, and I concluded to risk something by amputating at a point two inches above the line of demarcation and through the discolored tissues,

rather than take the other alternative of a knee-joint amputation. The flaps soon became gangrenous, however, and left the bone uncovered, and twenty days after the amputation I was called upon to remove the projecting bone. The gangrenous flesh had separated and the soft parts were then covered with granulations. I removed the bone and expected that the stump would heal rapidly by granulation. I was again disappointed, however, as the soft parts again retracted, leaving the bone exposed, and on November 1st the patient was brought to Mercy Hospital, where I made a reamputation at the beginning of the upper third. He then did nicely and was soon discharged with a sound stump. An examination of the amputated foot disclosed the fact that not a single bone was broken. This was a remarkable fact when it is considered that the soft parts were literally crushed to a jelly and their vitality entirely destroyed. While this case is not one of a compound fracture I have included it in this paper because the injury was of essentially the same nature, and involved the same considerations as would a fracture case.

CASE V.—A. B. was admitted to Mercy Hospital January 22, 1895, having been brought sixteen miles in a sleigh on an exceedingly cold night. His left leg had been caught between two logs and a compound, comminuted fracture of the tibia and fibula sustained. The first metatarsal bone had also been fractured, and a portion of the bone was torn from its attachments, forced through the skin, stocking and boot, and thrown a distance of several feet from the foot. I saw him a half hour after his reception at the Hospital, when he was nearly dead from cold and loss of blood. The leg had been tightly constricted for several hours and was black and cold, especially over the top of the foot. A fragment of the tibia I found upon the leg at some distance from the wound, and, as I have stated, the greater portion of the first metatarsal bone was missing altogether. At that time I had no thought of saving the leg, but, as the patient was in no condition for an operation, I directed that stimulants be given him and that his leg be surrounded with hot water bottles. I also had the leg irrigated and covered with bichlorid gauze, but made no attempt to place the bones in apposition. The following morning the foot was still cold, black, and swollen, and his general condition was very bad. I made a number of punctures in the dorsal surface of the foot from which exuded colorless serum in large quantities. During the day his general condition improved and arrangements were made to amputate the leg on the morning of the 24th. Other physicians were invited to be present at the amputation, and all our arrangements had been made for that procedure, when I found that much of the discoloration had disappeared from the foot, that it was warm and would bleed when pricked. With the concurrence of my colleague, Dr. Burkart, I concluded to defer the amputation. I wish to say that none of us would have thought of attempting to save this limb had it not been for the encouragement received from the report of Dr. Maclean's case, and this man owes a very good leg to the fact that the doctor reported that case so promptly. We followed Dr. Maclean's advice and made no attempt to reduce the fracture or do anything at all with the leg until the inflammatory reaction had subsided. Then with the chain-saw we removed the splintered ends of the tibia and wired the fragments together. Subsequent events demonstrated that we should at the same time have amputated the large toe, which had lost its metatarsal bone, but acting on the theory of doing as little as possible, we left the toe and packed the cavity from which the metatarsal bone had been extruded with iodoform gauze. All went well for several weeks and the fractured tibia united very nicely. A large piece of skin sloughed off from the sole of the foot and the back of the heel, but the resulting ulcers healed nicely by granulation. Then suppuration commenced in the tissues of the foot, quickly followed by necrosis of the metatarsal bones. We made free openings, used the curette freely, and eventually removed all of the metatarsal bones. Fortunately, the destructive process became arrested at this point, the foot filled in and in time became entirely sound. The toes dropped back to some extent owing to the loss of the metatarsals, and when healed the foot was shorter than the other, but he had motion at the ankle, a firm foot, fully as useful for the purpose of locomotion as the other one. His leg was two inches shorter than before, but by the use of a high-heeled shoe he is able to walk very nicely without a cane. He was discharged from the Hospital July 23, 1895, six months after admission.

CASE VI.—C. S. was admitted to Mercy Hospital, April 10, 1895. He had sustained a fracture of the right femur eight weeks before, which had been put up in the usual manner with Buck's Extension Apparatus by the attending surgeon, Dr. Foster of East Jordan, Mich. Union failed to occur and after eight weeks the patient came to Big Rapids, thoroughly dissatisfied with his doctor and determined on a malpractice suit as soon as he recovered. I found a fracture in the lower third of the thigh with no union whatever, and made an incision on the outer side of the leg over the seat of the fracture. The bone had been broken in the course of attachment of the adductor magnus, and a large band of muscular tissue had been drawn between the fragments holding them apart, so that I found it impossible to bring them together without dividing the muscular band. When this had been done the fragments were exposed, the end of each cut off, and the freshened surfaces securely wired together. A spiral drainage-tube was introduced and the plaster-of-Paris dressing applied, a window being left for the exit of the drainage-tube. All went well for the first week; bloody oozing stopped, and the tube was removed. Subsequently localized suppuration occurred, necessitating the reintroduction of the tube. Under antiseptic irrigation the suppuration soon subsided, and the incision quickly healed. The bone united after some delay, and in two months the patient was discharged. Before his departure I convinced him that his doctor was not in the least to be blamed for the failure of the bone to unite, and thus averted the threatened suit. Dr. Foster wrote me recently that the patient had a good leg and was only troubled by a stiff knee, which resulted from the long confinement in a straight position. He declined to have anything done for this condition before leaving the Hospital.

CASE VII.—J. M. was injured about two o'clock in the morning October 8, 1895, by being caught in a belt. His right leg was drawn partially around a pulley, and fractured in the lower third. I saw him a half hour later in a most dirty habitation, and the boy himself was in about as filthy a condition as one can imagine, with six inches of the tibia denuded of its periosteum projecting through a hole in an exceedingly dirty trouser leg. Upon removing the trousers I discovered that a flap of skin had been torn loose from the anterior and inner sides of the leg. The apex of the flap was two inches above the inner maleolus and the base two inches below the knee. The base was attached, the flap having been made by the upper fragment of the tibia. As the leg had been drawn around the wheel, the bone had given away, and the upper fragment had torn through the soft parts, producing the large V-shaped flap described. The fracture in the tibia was a very oblique one extending through a space of three inches in the shaft of the bone. The fibula was, of course, fractured, but was not exposed to view. I requested the people to move the boy to the Hospital and met with a refusal. I then informed them that I should not attempt to save the leg in that house, that the surroundings were so dirty that no good results could be expected, and that they must take their choice of an immediate amputation or a removal to the Hospital, where I would attempt to save the leg, but that I was by no means certain of achieving that desirable result. The alternative quickly brought the family to their senses, and the patient was transferred to the operating-room at the Hospital; where we turned the hose on the patient and gave him such a cleansing as he had evidently never before had. The broken tibia was then brought in position, and secured by a silver wire suture passed transversely through the oblique fracture. Ragged fragments of tissue were removed and the V-shaped flap carefully sewed in position. Large gauze dressings were then applied and the leg placed on a posterior felt splint. The tissues had been so much bruised and lacerated that during the following week enormous quantities of bloody serum exuded from the leg. In a few days the silver wire suture became broken and was removed but no displacement of the bone occurred. A half inch margin of the V-shaped flap sloughed off. The remainder became united, and the space left by the sloughing tissue quickly filled in by granulation. At no time was there any evidence of suppuration. In six weeks the entire wound excepting the small point at the apex of the flap had firmly healed. At the apex the tip of the upper fragment of the bone was exposed, and did not cover with granulations. As the bone itself had united and as there was no suppuration, I determined to let Nature take her course for a time and permitted the boy to move around on crutches. On January 1, 1896, the bone having become firmly united, the patient left the Hospital and came to my office occasionally to have the leg dressed. A month later a thin shell of bone separated from the inner surface of the tibia, and I removed it with forceps. After that the small wound rapidly closed by granulation, and the boy was dismissed from observation about March 1st.

These cases have been selected as illustrating the improved results that may be expected from increased experience. They cover the period of my connection with Mercy Hospital and present, I hope, some evidence of professional advancement during the past six years. In cases V and VII, who to-day have good legs, I should certainly have amputated so recently as two years ago without a thought that there was the slightest probability of saving the limbs. I trust that these reports may encourage others to perseverance in the same direction when similar injuries are encountered.

MEDICAL PROGRESS.

Vibrations and Fatigue in Bicycle Riding. — TURNER reports in the *British Medical Journal* for May 16, 1896, the conclusions from a large number of experiments made in order to determine the effect of vibrations upon the body. The symptoms which usually follow a hard bicycle ride and which used to be attributed to vibration are sleeplessness, thirst, want of appetite, followed by lassitude, headache, and in severe cases, palpitation of the heart and great depression. No such symptoms are complained of by engineers nor firemen, nor were experienced by Turner after a one hundred mile ride on the front of an engine, though the vibration in that situation was much greater than occurs on any bicycle. A comparison of the excreta after hard rides with pneumatic and solid tired bicycles showed that the body waste was from ten to twenty per cent. greater with the latter, the exact amount varying according to the conditions of road and weather, and due evidently to the excess of power which was necessary to propel the solid-tired wheel, and not to excessive vibration. To make this quite certain, Turner rode twenty-five miles on a perfectly smooth track on a tricycle, shod with two-inch pneumatic tires, and an easy spring and large saddle. Vibration was at a minimum. A high wind was blowing, and as he was not in training and rode about eighteen miles an hour, he finished quite exhausted. He suffered from every symptom supposed to be due to vibration, and that night had a temperature of 102.6°. All unpleasant symptoms subsided after forty-eight hours' rest. The lesson is obvious, that, although vibration has been greatly lessened by the pneumatic tire, the danger from over-fatigue is the same as ever.

A Fetus in the Abdomen of a Man.—A remarkable case was presented before the Academy of Medicine (Paris) by LÉVY (*La Semaine Méd.*, May 6, 1896). A young man, aged nineteen, suffered for two years with an abdominal tumor. At operation, this tumor, which had grown to the size of a child's head, was found to be situated retroperitoneally between the mesenteric reduplications. It contained a yellow gelatinous fluid, and a female fetus of about the fifth month of development. The patient died twenty-four hours after operation.

The tumor was evidently to be classed among the dermoids, and was really a rudimentary twin, which after a long period of inactivity had resumed its development, and the fetus was therefore the sister and not the daughter of the patient.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,

SATURDAY, JULY 18, 1896.

THE "DRINK CURE" IN BELLEVUE HOSPITAL.

IN a previous issue we called attention to the fact that the Commissioners of Charities in this city had set apart a ward in Bellevue Hospital for the trial of a secret "cure" for drunkenness, and that the experiment was to be carried out under the immediate surveillance of the proprietor of the remedy.

The experiment has now been completed, a fulsome report has been forwarded to the Commissioners, and the daily press has prematurely heralded throughout the country the miraculous results which have been obtained by the use of Dr. Oppenheimer's cure.

The affront and indignity offered to the physicians of Bellevue Hospital and to the profession at large by this action of the Commissioners is unprecedented in the history of their office, or in the annals of Bellevue Hospital, and it is proper to make inquiry as to the cause which led to such an action. We can do so most effectively by recounting the evolutions of the "cure." A few years ago the proprietor, who was a physician in good standing, circulated among the profession a printed communication in which he set forth that he had been unusually successful in the treatment of alcoholism, and that he would be glad to take charge of such patients, for physicians, at his house which he had converted into a sanitarium. The fact that a stock company had been organized for the treatment of inebriety by a secret measure was not mentioned. It was not until attempts were undertaken to dispose of the rights to utilize the substance in European territory, and a reorganization of the company and redistribution of the stock was made that the unwholesome aspects of the scheme came to light. That our readers may know the full scope of the undertaking and the character of the men who are advancing this enterprise, we publish in another column a nearly complete copy of the charter of the company.

That the project might have a show of respectability the names of five reputable physicians were given, who, it was said, had consented to become consultants to the Sanitarium. It came to light, however, that some of them had accepted a financial interest in the company without returning a monetary *quid pro quo*. Further gifts of stock were made among the profession and elsewhere, and so advantageously placed was this generosity that the road to his honor, the Mayor, was made easy. The motives which prompted the Mayor to urge the Commissioners, against the better judgment of the minority of that Board, to establish an unprecedented, unwarranted and unjustifiable foothold for the use of secret preparations in the hospitals under their jurisdiction can only be surmised.

The counsel of those best qualified by years of training and experience as to the advisability of such a revolutionary procedure was not sought, nor was it politely received when given unasked.

Despite the opposition of the entire Medical Board, in the face of the personal appeals of unbiased and tolerant individuals capable of clearly seeing the outcome of such a procedure, the Commissioners set apart a ward for the experimental use of a substance, the constitution of which was known to its proprietor alone. Examples of favoritism have not been wanting in previous adminis-

trations, but none surely that can in any way approach this.

A few days of trial of the politically fostered "cure" has convinced the "Experimenting Board of Commissioners" that "there is something in it." A second Keeley cure, forsooth! It has likewise convinced others that "there is something in it," viz: shares of the stock of a company which, by reason of the boom to be given by its introduction into Bellevue, promises good dividends.

At the present time the office-room of the Charity Commissioners is like the sanctum of a popular patent medicine proprietor, testimonials from grateful patients "cured," abound; while the individual member of the Commission, who has taken such a suspiciously personal interest in the experiment, is busying himself visiting "cured" cases and verifying testimonials, labor for which the Commonwealth pays him $5000 a year. The New York daily press, in the meantime, is publishing affidavits of men who have been through the "cure" and pronounce it entirely worthless.

In the future we may expect Bellevue Hospital to be made the arena where any individual with a "cure" for consumption, or the tobacco habit, or inebriety, or even for the unsavory big "G," if a reporter, an editor, and a few physicians be properly subsidized, can demonstrate that "there is something in it,"—a possession equal to a scientific corrollary for the present Commissioners. We hereby call the attention of any one in possession of such a "cure," and likewise any one who can think of a cure before the present Commission expires, that there is in New York City a magnificiently equipped hospital, with an unexcelled visiting and house staff, which is at their disposal, and which they can have for the asking, according to the precedent just established.

PRECAUTIONS IN THE PROPHYLACTIC USE OF THE ANTITOXIN OF DIPHTHERIA.

Adamkiewicz, in the *Wiener med. Presse* for May 3d, attempts an explanation of the cause of death, or alarming symptoms, subsequent to injections of *heil-serum* for the preventive treatment of the healthy. He first considers the argument brought forward by Langerhaus of Berlin, who recently had a fatal case of this nature in his own family. The latter attributed the death to the poisonous action of the antitoxin upon a healthy subject when unneutralized by a preëxistent toxin. This seems *a priori* improbable considering the large number of cases of suspected diphtheria which have been treated by antitoxin without ill-effects, and in which the suspicion has been proved unfounded. Nor does the evidence show that the injection of serum into a vein is in all cases *per se* an element of danger, since the blood is able to tolerate the introduction of considerable quantities of indifferent substances with impunity. That the fatality was due to the amount of carbolic acid in the injection is not in accordance with the known effects of that substance, and the death was far too sudden to have resulted from poisoning by the serum itself, serum intoxication having been shown by Eulenburg to be always a more or less chronic process.

The entrance of the serum into a vein and its employment in too concentrated a form having also been excluded, one is compelled to seek another cause for the intensification of its action in this case. This Adamkiewicz finds in a disturbance of the adaptive mechanism of the organism. The living body is provided with a self-regulating apparatus which protects it against noxious influences within certain limits; once these are passed the animal is lost. In his recent experiments with "cancroin" he found that several patients showed without apparent reason alarming signs of collapse after injection; and by careful exclusion was forced to conclude that the cause was sudden passage beyond the bounds of the regulating mechanism. This was confirmed by the discovery that no such effects resulted when the injection was gradually given so as to allow the organism time for adaptation; in consequence of this Adamkiewicz now injects "cancroin" in tenths of a cubic centimeter, allowing some seconds after each injection for the self-regulating mechanism to act.

He further extended his experiments to the injection of atmospheric air into the veins of a guinea-pig, and found that a considerable quantity could be taken up and eliminated without danger if it were given in small doses; thus 10 c.cm. injected in this way produced no ill-effects, while 2 c.cm. were instantly fatal when injected at

once and forcibly. Any substance, serum included, may have a double noxious action when introduced into the body, proportional to, first, the force with which it is injected, and secondly, the specificity with which it acts on the blood or through the blood on other constituents of the body. The virulence increases with the force of injection, and this may well account for the death under consideration.

RESUME OF RECENT PROGRESS IN ORTHOPEDICS.

THE OUTGROWING OF DEFORMITY.

THE closer search for first causes, which has been stimulated by the development of orthopedic surgery in the direction of prevention, as well as toward a broader and more effective treatment of deformity, has made it, more than ever before, evident that a large proportion of the disabilities of later life have their origin in early childhood; and many deformities which, in the sense of perfect cure, are hopeless when advice is asked, belong to the class that is popularly supposed to become outgrown. In estimating the value of the evidence that supports this belief, one must bear in mind the fact that the popular standard of symmetry is a low one, and that minor disabilities receive no consideration whatever. One need not look farther than the foot for an example to support this statement, for the accepted type of beauty of this useful member, at least, when it is concealed by the shoe, is one of deformity and evident disability.

If one asks the reason for an individual faith in the outgrowth of deformity, he will usually find it rests upon the fact that bowed legs become straight or straighter as they increase in length; and it is because of this proof of the corrective power of nature that a mother has expected it may be, to see the slowly increasing hump of Pott's disease finally disappear! That bowed legs, even, are not always outgrown, is easily demonstrated by observation on the streets of the city; and it is certain also that if the deformity is less marked in the adult than in the child, the moral discomfort produced by it is correspondingly greater.

However strong may be one's faith in the outgrowth of deformity, he will admit, doubtless, that a straight child is more likely to become a straight man than a crooked child, and that correction may be more effectively applied at an early than at a later period. The growing child has often been compared to the growing plant or tree that may be trained toward symmetry, or that, by neglect or accident, may become inclined toward deformity. Trees and children have the same inherent force that tends to overcome deformity, but those who wish to produce straight trees watch for the beginning of distortion, and if it may not be quickly corrected, the tree is rooted out and replaced. Children thus differ from trees, in that they are neither selected, nor can they be replaced by more promising specimens, and it would seem, therefore, that all the more care and vigilance should be exerted in preventing deformity, or in correcting it in the early stages of its development.

If, then, one is to trust in this power of nature to overcome deformity, he should have a clear apprehension of the reasons for his faith, that he may compare intelligently the probability of its realization with the danger of the neglect of timely treatment.

In the popular mind, the seriousness of deformity depends entirely upon its noticability; from this point of view, the question of outgrowth depends upon its relative proportion to the body. If it remains stationary, it will become less marked as the body increases in size, until it may finally disappear. But deformity is not, as is popularly supposed, an entity; it proceeds from many causes, and it may be divided, therefore, into many classes; but for the present purpose, two will suffice: One in which outgrowth is impossible, and another in which it is possible or probable under favorable circumstances. In the first class may be placed the congenital distortions and those which are the result of permanent injury, as from paralysis or bone or joint disease. In the second class may be included the bowed legs, the knock-knees, the weak feet, the loose joints, the round backs, the flat chests, and the like. These are often called postural deformities, because whatever may have been the first impulse toward distortion, its development is due to the influence of the force of gravity, which, in man, is more difficult to withstand, because of the upright posture which he alone assumes. This influence will be

more marked if the structure of the body is inadequate to the strain of normal use, either because of an inherited deficiency of vital energy, or because of acquired weakness, of which rachitis furnishes a familiar example. This deforming influence will be increased if the body is subjected constantly to its effects, as by the necessity for fixed attitudes to the point of fatigue in place of the constant change normal in childhood. The tendency to deformity will be favored if improper attitudes are assumed or induced by uncomfortable seats, or less directly by imperfections of eyesight or by habitual occupations in which deforming postures are assumed, influences which often work to the disadvantage of school-children. The outgrowth of deformity of this class will require an accumulation of vital force sufficient not only to withstand the force of gravity, but to draw the weakened and distorted part toward symmetry.

The natural life of the country has long been celebrated as providing the most favorable conditions for the spontaneous cure of weakness and distortion, but such complete reversal of the conditions of life is not always necessary or possible, nor is it always effective. In many instances the body may be inclined toward symmetry by simply avoiding deforming influences, which are not a necessary part of its environment, and by lessening the burdens put upon the weak child until it may be strengthened to withstand them. It is interesting to note in this connection that the term orthopedy, now modernized into orthopedic surgery, was invented by Andry, 150 years ago, to signify the treatment of the more common deformities of childhood by the simple means that might be applied by parents and nurses, and such treatment is still adequate if properly directed and seasonably employed.

The force of nature that tends to the outgrowth of deformity is a blind force, that is much less powerful in the higher than in the lower forms of life. It may be effectively utilized and guided in the face of adverse circumstances, and it may prove impotent when unassisted, even though every condition be favorable. If, then, faith in the inherent power of nature to overcome deformity is to be synonymous with neglect, it may well be replaced by a disbelief that would at least require favoring conditions for the evolution of individual deformity to symmetry.

ROYAL WHITMAN, M.D.

ECHOES AND NEWS.

Casualities of July 4th.—Two deaths occurred in Brooklyn last week from tetanus. Both were from wounds caused by firing blank cartridges from filthy toy pistols at close range on Independence day.

A New York Hospital Appointment Declined.—Dr. Thomas H. Manley, visiting surgeon to the Harlem Hospital, since it was opened ten years ago, was lately offered a position as consulting surgeon to the same service, but declined.

British Physicians.—Great Britain has on her *Medical* Register 35,000 names. Nearly 10,000 have been added during the past ten years.

A Swindler Arrested.—For several months a number of the New York hospitals have been victimized by a man representing himself as the agent of an express company, and in this capacity he collected excessive bills upon goods that never arrived. On trying this game upon the matron of the New Amsterdam Eye and Ear Hospital, his character was recognized and he was promptly arrested and convicted.

A Statue of Pasteur. — Pasteur's statue is soon to be placed in the market place at Alais, France, to commemorate his discovery of the remedies for diseases of the silkworm. It was at Alais that this work was done by the savant.

Poisonous Extracts.—Owing to the recent death of two children in Philadelphia, attributed to eating "snowballs"—a very cheap variety of water-ice sold on the streets—an analysis was undertaken by Dr. Henry Leffmann. Dr. Leffmann found the extracts used were artificial in some, containing fusel oil and analin dyes, and in others old and dangerously fermented.

Modern Psychology.—Professor Witmer of the University of Pennsylvania, will give during a summer course under the University extension auspices, twenty lectures upon this subject. In these he promises to touch upon such topics as hypnotism, phrenology, and palmistry, and will endeavor to extract any atom of truth that may exist amid the great mass of misconception and nonsensical speculation involved in these falsely called sciences. These are only incidentally treated, the real substance of his course will contain food for the strongest mental digestion.

Obituary.—Dr. Mary Elizabeth Grady of Brooklyn, who received her degree of medicine from the New York Medical College and Hospital in 1884, died at her home, June 29th, from consumption. Miss Grady, who was thirty-three years old, was also graduated from the New York Medical Ophthalmic Hospital College. She practised in Brooklyn, where she was born, and was visiting physician to the Brooklyn Memorial Hospital for Women and Children.

Dr. Samuel Sexton died in New York city, July 11th, aged sixty-three years. He received his medical degree from the University of Louisville in 1856; served during 1861 as surgeon of the Eighth Ohio Volunteers, and since that date has practised his profession in New York City. He was vice-president of the American Society of Otologists in 1886. He was for many years a surgeon of the West Side Eye and Ear Infirmary, and its chief in 1877; and was subsequently a lecturer at the New York Eye and Ear Infirmary. He wrote many articles concerning his specialty, and in 1888 published a work entitled "The Ear and its Diseases." In 1889, he was decorated by Venezuela with the medal of honor, and with admission to the rank of the third class, its highest honor, *el Busto del Libertador*. He was a member of the County Medical Society, the Academy of Medicine, and the Practitioners' Society, and of many clubs. Sexton was ingenious and inventive. He devised some instruments, and adapted an electric lamp for aural examination. He was one of the first American aural surgeons to develop in this country the operation of myringotomy, and operations on the ossicular chain, following Schwartze, Kessel, Lucæ, and others.

The American Dermatological Association.—The regular annual meeting of this Society will be held at the Hot Springs of Virginia, September 8, 9, and 10, 1896. Everything will be done to make the meeting a success, and several papers on interesting subjects have been already promised. Dr. White will open a general discussion on the subject, "What effect do Diet and Alcohol have upon the Causation and Course of the Eczematous Affections and Psoriasis?" The president, Dr. Charles W. Allen, can be relied upon to organize a most instructive and interesting meeting.

Diet and Disease.—From the report of the New York Institution for the Deaf and Dumb we learn that with an average of 400 pupils annually, aged from 2½ to 18 years, but one death has occurred in nine years among 3600 children; and this death was due to diphtheria contracted while absent from the Institution on vacation. The diet consists principally of beef and mutton, with few vegetables.

The State Board of Health and Street Refuse.—At the meeting of the State Board of Health, on June 30th, there was a discussion concerning the present manner of dumping the refuse of the city in the bay in such a place that it is carried back to the shore by the currents. Power was given to Dr. Smelzer, the secretary of the Board, to cooperate with Supervisor Delehanty of the Navy Department, in the adoption of a new system by which the present conditions will be changed, and the nuisance abated. Dr. Smelzer advocates towing the refuse ten miles beyond Sandy Hook.

Foreign Diplomas.—One of the most commendable features of the new medical law of Ohio is that it fails to recognize all foreign diplomas. The impossibility of discovering fraud and deception, when attempted by those interested in them, renders this step necessary. Besides, the examination required by the board will prove no hardship to those who really deserve recognition.

Intubation of the Duodenum.—Dr. Hemmeter has been making experiments by which he hopes to enable the surgeon to explore the duodenum by a tube inserted through the mouth. He first causes the patient to swallow a thin rubber bag with a groove along what will be its superior border. This is then inflated and the flexible tube is readily forced along this groove through the pylorus.

The American Public Health Association.—The twenty-fourth annual meeting of this Society will be held at Buffalo, N. Y., September 15–18, 1896. The Executive Committee have selected the following topics for consideration: (1) The Polution of Water Supplies; (2) The Disposal of Garbage and Refuse; (3) Animal Diseases and Animal Food; (4) The Nomenclature of Diseases and Forms of Statistics; (5) Protective Inoculations in Infectious Diseases; (6) National Health Legislation; (7) The Cause and Prevention of Diphtheria; (8) Causes and Prevention of Infant Mortality; (9) Car Sanitation; (10) The Prevention of the Spread of Yellow Fever; (11) Steamship and Steamboat Sanitation; (12) The Transportation and Disposal of the Dead; (13) The Use of Alcoholic Drinks from a Sanitary Standpoint; (14) The Centennial of Vaccination; (15) The Relation of Forestry to Public Health; (16) Transportation of Diseased Tissues by Mail; (17) River Conservancy Boards of Supervision. Upon all the above subjects special committees have been appointed. Papers will be received upon other sanitary and hygienic subjects also.

The Pearl and Rose Leaf.—Mr. Charles James Fox was well acquainted with Dr. Edward Jenner, and would have been well inclined to adopt the good doctor's views except for the fact that he had been prejudiced against the cow-pox by the antagonism of his family physician, Dr, Moseley. One day in playful vein he was bantering Dr. Jenner, and asked: "Pray Dr. Jenner, tell me in regard to the cow-pox, what is it like?" "Why, it is exactly like the section of a pearl on a rose leaf." This comparison, so true and so poetic, quite vanquished the scornful Mr. Fox.

Death After Anti-rabic Inoculation.—A lad of eighteen years was severely bitten on the hand in March, 1895, at Stockport, England, by a large dog that was subsequently proven to be rabid. On the fifth day thereafter, the boy was inoculated in the Pasteur Institute, Paris, and received treatment for eighteen days, when he was discharged. He frequently complained of pain in his wrists and ankles, and in the abdomen, where the injections were made, and never fully regained his health thereafter. For several weeks prior to his death, he experienced a tingling sensation in his injured hand and arm. On the night of June 19, 1896, he awoke crying with pains in this extremity; during the following day he had convulsions, and violent spasms of the respiratory muscles occurred when he attempted to swallow. He died with characteristic symptoms on June 20th, at 2.30 A.M.

Academy Headache.—Mr. Simeon Snell of Sheffield, England, reports in the *Medical Press and Circular* a form of headache to which he has given the above name. It has long been appreciated by a large number of those who frequent picture galleries that a few hours spent in steadily observing the paintings will almost invariably be succeeded by a headache. Mr. Snell, while investigating the causes of miner's nystagmus, a disease he has recently discussed in a most classical manner, has also discovered that the reason for these troublesome encephalalgias lies in a strain of the external muscles of the eye—especially the superior rectus and levator palpebræ. As compared with the other external ocular muscles these are known to be feeble and the continued exertion to which they are subjected, in directing the vision to those pictures hung above the line will readily account for the painful results. If the head is held well back the necessity for rotating the eyes upward may be obviated in part and the evil effect accordingly diminished.

Appointment of Dr. Barlow.—Dr. Thomas Barlow, Examiner in Medicine at the Victoria University, has been appointed Physician to the Household in Ordinary to Her Majesty. This honorable position was held, until his recent death, by the late Sir John Russell Reynolds.

The Cholera Bacillus in Europe.—Last week Professor Koch was called to Dantzig to examine the possible source of infection from which one man had died. The bacillus of cholera was discovered, but Professor Koch expressed his doubt as to its virulence being sufficient to justify fears of an epidemic.

Changes in Belgian Universities.—At both Ghent and Liége the government has made provision for increasing the number of professors in order that special branches of medicine and surgery may be more extensively taught.

CORRESPONDENCE.

QUACKERY IN BELLEVUE HOSPITAL.

To the Editor of THE MEDICAL NEWS:

DEAR SIR: In an editorial in issue of MEDICAL NEWS, dated June 27th, and entitled "The Commissioners of Charities of New York City, and a Secret Cure for Drunkenness," the action of the Commissioners of Charities in allowing quackery to secure a foothold in Bellevue Hospital is *deplored*.

This is certainly moderate language for the harshest insult ever imposed on the Medical Board of Bellevue Hospital since its organization; but for even this installment of independence, the profession at large should feel grateful, as no other medical journal in New York has taken any notice of the matter, much less hurl those anathemas of condemnation at its instigators, which they richly deserve.

Perhaps the editor is not aware of the fact that this secret remedy is owned and controlled by a stock company. The writer is cognizant of an instance in which a practitioner of this city was offered stock if he would allow his name to be used by the concern; and another, in which the proposition was indignantly refused.

The superintendent plumber lauds the remedy (!). May he not be another stockholder, anxious to give it a boom and swell his returns?

The attitude of the Medical Board of Bellevue Hospital in this instance is a matter of no consequence to the Commissioners. No. Mr. Editor, without a code, without discipline, or penalties, the body medical is in a chaotic state, and it looks very much as if that prophecy of a late venerable physician was about to be realized; who predicted that the time was near when New York would witness the greatest reign of quackery ever known in its history. When, indeed, does history record such a triumph of charlatanism, with the chief magistrate of a great city to encourage it, and one of the largest hospitals in the world with its portals wide open to receive it?

AN OBSERVER.

NEW YORK,
July 11th.

SPECIAL ARTICLE.

THE COMMISSIONERS OF CHARITIES make the following statement to the MEDICAL NEWS as to the manner in which Ward No. 33 in Bellevue Hospital has been set aside for private experimentation by Dr. Oppenheimer, with his secret remedy for alcoholism: "It was largely due to the suggestion of the Mayor, who had become impressed with the 'cure,' and advised that we consider the question of its introduction into the alcoholic ward of Bellevue Hospital. In the early part of May the attention of the Commissioners was called to the Oppenheimer treatment, and several cases came to our notice, one under the direct observation of one of the commissioners." The Medical Board of Bellevue Hospital collectively and individually remonstrated with the Commissioners, but to no avail. They had the power and were going to use it. A copy of the charter of the Hygeia Institute, of which Dr. Oppenheimer appears as president, is appended.

CERTIFICATE OF INCORPORATION OF THE HYGEIA INSTITUTE.

THIS IS TO CERTIFY that we, Jay Cæsar Guggenheimer, Theodore L. Hermann, Anthony J. Dittmar, Joseph A. Arnold, and Benjamin F. Kraft, all citizens of the United States, and citizens and residents of the City, County, and State of New York, are desirous of organizing a corporation, and do hereby form a corporation, pursuant to the laws and statutes of the State of New York, and we do hereby make, sign, acknowledge, and file this certificate for that purpose, as follows:

First. The name of the corporation is to be "Hygeia Institute."

Second. The objects for which the corporation is formed and the nature and locality of its business are as follows:

1. To conduct the business of managing hospitals and sanitariums for the cure of persons addicted to the excess-

ive use of alcoholic, malt, or spirituous liquors, intoxicating drinks, or narcotic drugs, in any and all States and Territories of the United States.

2. To buy, sell, exchange, acquire, lease, rent, or otherwise deal in any real estate for the purpose of conducting and carrying on the business above set forth.

3. To apply for, obtain, purchase, or otherwise acquire any patents, brevetes d' invention, licenses, and the like in respect of any inventions and discoveries which may seem capable of being used for any of the purposes of the company, and to use, exercise, develop, and grant licenses in respect of, and otherwise turn into account the same.

4. To cause or allow the legal title, estate, and interest in any property acquired, established, or carried on by the company, and to remain or be vested or registered in the name of or carried on by any other company or companies, foreign or domestic, formed or to be formed, and either upon trusts for or as agents or nominees of this company, or upon any other terms or conditions which the board of directors may consider for the benefit of this company, and to manage the affairs or take over and carry on the business of such company or companies so formed or to be formed, either by acquiring the shares, stocks, or other securities thereof or otherwise howsoever, and to exercise all or any of the powers of holders of shares, stocks, or securities thereof, and to receive and distribute as profits the dividends and interest on such shares, stocks, or securities, and generally to exercise all the powers capable of being conferred by section forty of "The Stock Corporations Law," as amended by chapter 688 of the laws of 1892.

Third. The amount of the capital stock shall be three hundred thousand dollars ($300,000), all consisting of common stock divided into three thousand shares of the par value of one hundred dollars each.

Fourth. The business of the company is to be transacted and located principally in the State of New York, but may be transacted and located in all of the States and Territories of the United States, and in foreign countries.

Fifth. Its principal business office will be in the City, County, and State of New York, but it may establish offices in such other States and Territories, and such foreign countries, as will best promote the purposes of its organization, as above specified.

Sixth. The number of its directors shall be five, each of whom shall be a stockholder, having at least five shares of stock.

Seventh. The names and post-office addresses of the directors for the first year will be as follows:

JAY CÆSAR GUGGENHEIMER, 69 East Ninetieth street,
THEODORE L. HERMANN, 1074 Madison avenue,
ANTHONY J. DITTMAR, 12 East 110th street,
JOSEPH A. ARNOLD, 103 West Seventieth street,
BENJAMIN F. KRAFT, 16 East Seventy-sixth street,
All in the City, County, and State of New York.

Eighth. The post-office addresses of the subscribers are as above stated, and each of them agrees to take five shares of stock in the corporation.

IN WITNESS WHEREOF, we, the subscribers, have made, signed, and acknowledged this certificate in duplicate, this 11th day of October, 1894.

JAY CÆSAR GUGGENHEIMER.
THEODORE L. HERMANN.
ANTHONY J. DITTMAR.
JOSEPH A. ARNOLD.
BENJAMIN F. KRAFT.

STATE OF NEW YORK, }
CITY AND COUNTY OF NEW YORK, } ss.:

On this 11th day of October, 1894, before me personally came, Jay Cæsar Guggenheimer, Theodore L. Hermann, Anthony J. Dittmar, Joseph A. Arnold, and Benjamin F. Kraft, all to me known, and known to me to be the individuals described in and who executed the foregoing instrument, and who to me severally acknowledged that they executed the same.

EDW. J. DWYER,
Commissioner of Deeds,
City and County of New York.

ADDENDUM.

October 30, 1894: Isaac Oppenheimer, M.D., president; Juliet Mendel, treasurer; and Theo. L. Hermann, the three constituting a majority of the directors of the Hygeia Institute, filed a sworn certificate that the capital stock had been paid in.

SOCIETY PROCEEDINGS.

ONE HUNDRED AND FIFTEENTH ANNIVERSARY OF THE MASSACHUSSETTS MEDICAL SOCIETY, HELD IN BOSTON, JUNE 9 AND 10, 1896.

FRANK K. PADDOCK, M.D., of Pittsfield, President.

THE SHATTUCK LECTURE, "THE SURGERY OF TYPHOID FEVER."

by W. W. KEEN, M.D., of Philadelphia.

HE said that twenty years ago, in delivering the Fifth Toner Lecture, he had discussed the complications and sequelæ of typhoid fever, and he now desired to supplement that lecture with a consideration of the surgery of typhoid fever, more particularly the occurrence of gangrene as a complication. During the last twenty years our views on the pathology of typhoid fever had undergone some very radical changes, but the clinical facts and deductions remain as true now as when the original lecture was delivered.

Singularly enough, he said, the occurrence of gangrene as a complication of typhoid fever, has received but little attention from either physicians or surgeons. Bourgeois, in 1857, had furnished the first serious contribution. One would suppose that gangrene would follow only severe attacks, but a large number of cases had been reported after mild attacks of the disease, so that it behooved the physician to be ever on the alert for its occurrence. It was, however, such a comparatively rare occurreuce, that men of such wide experience as Flint and Murclusion have never seen a case. Unlike the bone lesions, gangrene is not a very late sequel. As the presence of the typhoid germs had been demonstrated in the bones eighteen

months, and even six and eight years after the typhoid fever, the late occurrence of the osseous complications could be readily understood. Gangrene, on the other hand, is most commonly observed in the second or third week of the disease, never having been observed before the fourteenth day, or after the seventh week. Its development at this time may be ascribed (1) to the stronger vitality and power of resistance at the beginning; and (2) to the fact that a certain length of time is requisite for the diffusion of the bacilli and their toxic products.

Dr. Keen said, that in his former lecture he had stated that he considered gangrene due to three factors, viz.: (1) the altered blood state; (2) the weakened heart action; and (3) the mechanical difficulty of carrying on the circulation, especially in distant parts; and that all these factors acted by producing thrombi. But since the discovery of the typhoid bacillus, our views had been necessarily somewhat changed. The parts which should be specially subjected to bacteriological examination are: (1) The endocardium; (2) the endocardial clots; (3) the walls of the arteries and veins at the points of obstruction; (4) the thrombi or emboli; (5) the perivascular tissues in this neighborhood; and (6) if no coagula are visible, the gangrenous tissues themselves. Vincent had directed special attention to the significance of mixed infection. Experiment had shown that the staphylococcus was remarkably inimical to the growth of the typhoid bacillus, but that when mixed with streptococci, the typhoid bacilli grew vigorously. In 41 cases of typhoid fever combined with various suppurative processes, it was found that in 32 the complication was due to the aureus or albus. All of these cases recovered in spite of multiple suppuration and periostitis. On the other hand, in 8 cases in which the streptococcus was present, 5 died, showing a striking difference in the fatality of the two varieties of mixed infection. The typhoid bacilli are most numerous in the blood during the first twelve days, and from that time on diminish rapidly, and are only found exceptionally in the fifth or sixth week. They probably reach the blood through the lymphatics. They have been found occasionally in organs which could only be reached by the blood where there is arterial thrombosis, the resulting gangrene is usually dry; but occasionally the veins become obstructed, and then a part or all of a limb may fall into sudden ruin from moist gangrene. Numerous bacteriological examinations now make it reasonable to believe that when the typhoid bacilli are found in pure culture in an abscess, they are its pathological cause.

The speaker said that the cause of the gangrene was obstruction of the circulation, and this obstruction prevented itself in four varieties, viz.: (1) Arterial emboli of cardiac origin; (2) arterial thrombosis arising in the vessel itself; (3) venous thrombosis of the same order; and (4) thrombi in the peripheral vessels. As the circulation was not so completely cut off in venous, as in arterial thrombosis, gangrene was not so likely to result from venous thrombosis. In both varieties, but particularly in the arterial form, the clots are often discontinuous. Occasionally, venous thrombosis was followed by sudden death. Both forms of thrombosis are apt to give rise to a symmetrical gangrene which closely resembles Reynaud's disease.

Regarding the symptoms, it might be said that toward the end of the fever, or early in convalescence, a sudden, severe, and persistent pain would be felt either at the seat of the gangrene, or in the obstructed part, and radiating to the periphery. Following this there would be coldness, numbness, discoloration, and the other usual evidences of gangrene. The pulsation of the affected vessel near the gangrenous area would be found quite feeble, and near the obstructed portion the vessel would feel like a cord. When the primary obstruction was in the vein, and was extensive, it was very apt to be symmetrical. In his Toner lecture he had reported 113 cases of gangrene. To this he could now add 90, or a total of 203 reported cases in fifty years. Age had but little influence on gangrene in connection with typhoid fever, but not so with sex, for, out of 155 cases, 90 were males and 65 females. In 214 cases in which the location of the gangrene was studied; in 146 it was in the lower extremities and genitals, and in 16 in such peripheral distributions of the vascular system as the ears and nose. Gangrene, due to venous thrombosis, is most commonly found in the lower extremities. Of 41 arterial cases, 18 occurred in the third week; of 107 venous cases, 40 occurred in the third week—in other words, 58, or 39.2 per cent. developed in the second or third weeks. Just as in gangrene from other causes—often of non-bacterial origin—the legs suffer more than the other parts of the body; but of 46 cases of arterial gangrene, 8 involved both sides, 19 the right side, and the same number the left side. On the other hand, in the venous cases, both sides were affected in only 4 instances, the right in 10, and the left in 38. He was of the opinion that the left side was more often affected, because the left common iliac vein is subjected to compression as it passes under the right common iliac artery. Gangrene of the genitals was more commonly seen in older subjects.

As to treatment, it might well be said that the most important was the preventive treatment, *e.g.*, the securing of good food and air; aiding the flagging heart by alcoholic and other cardiac stimulants, and stimulating the peripheral circulation by faradization. In giving baths great care should be taken to avoid bruising the body or limbs. After gangrene was actually present, the important thing was to keep the parts clean by the application of an antiseptic dressing. In gangrene of the head and neck, operative interference was, of course, limited to the removal of the gangrenous tissue. Where amputation is demanded it should not be done until a final line of demarcation had formed. The leg should be emptied of blood by elevating it, but the elastic bandage should not be employed, but by its compression, an already existing thrombus might be broken up, or septic matter forced into the general circulation. Owing to the obstruction to the circulation, the bleeding will naturally be less than usual, but it should be constantly borne in mind that such patients have not one drop of blood to lose. The surgeon should not delay amputation long after the line of demarcation had formed.

Section on Medicine.

Dr. A. L. Mason of Boston, chairman.

J. H. McCollom, M.D., of Boston, read a paper on

diphtheria antitoxin.

He said that diphtheria antitoxin had been on trial for something over three years now, and the consensus of opinion was that it was a remedy of great value in the treatment of diphtheria. In the Boston City Hospital, in 1891, 237 cases of diphtheria was treated, with 105 deaths; in 1892–93, 387, with 185 deaths; in 1893–94, 438, with 203 deaths; in 1894–95, when antitoxin was used in only a few cases, 698 cases were treated with 266 deaths. This gave a total of 1760 cases treated, with 759 deaths, or 43 per cent., which was about the average death-rate in the hospitals, both in this country and in Europe, before the introduction of antitoxin. In the City of Boston, from 1878 to 1894, the average death-rate in the city at large was 30.7 per cent.; the lowest death-rate having been 27.18 per cent., and the highest 35.7 per cent. We thus have a total of 24,813 cases from which to determine the average fatality of the disease. From September 1, 1895, to May 1, 1896, in the Boston City Hospital, 1359 cases were treated with antitoxin, with 170 deaths, or a mortality of 12.51 per cent. Most of these cases were severe. In 1895, 4059 cases of diphtheria were reported to the Board of Health, and 588 deaths, or a mortality of 14.48 per cent. These cases include many mild ones, and some of them were undoubtedly treated with antitoxin, but just how many it was impossible to determine. To show the influence of age, the following statistics were given of the cases admitted during eight months, all of them receiving antitoxin: Seventeen under one year, 3 deaths, or 17.6 per cent.; 74 from one to two years, 20 deaths, or 27 per cent.; 136 between two and three years, 37 deaths, or 27 per cent.; 329 between three and five years, 55 deaths, or 16.7 per cent.; 410 between five and ten years, 39 deaths, or 9.5 per cent.; 187 between ten and twenty years, 9 deaths, or 4.8 per cent., and 206 twenty years old and upward, 7 deaths, or 3.4 per cent. The highest death-rate—27 per cent.—was naturally in those under three years old, yet when this is compared with the death-rate before the introduction of antitoxin—46 per cent.—it is evident that the mortality has been greatly reduced. In all of these cases the antitoxin was administered shortly after their admission, and although a bacteriological examination was made in every instance, it was not thought wise to delay the use of the serum until the result of such examination had been made known. Of the 1359 cases admitted, 53 died within a very few hours after admission; if these were eliminated the mortality would be only 8.9 per cent. If the 74 deaths occurring within 48 hours after admission were included, the mortality would be reduced to 7.4 per cent. In many of the operative cases a very marked improvement followed the use of the antitoxin. Prior to January, 1895, the mortality in the intubated cases was 83 per cent., as against a mortality of 46 per cent. in the last few months. It seems reasonable to suppose that this is due to the influence of the antitoxin. The antitoxin employed in the Hospital was that prepared by Dr. H. C. Ernst, of which the usual initial dose was 5 to 10 cc.

The speaker said that after the injection of antitoxin the membrane would be seen to become detached at the edges and to present an appearance so characteristic that he was willing to assert that he could go through a ward, and, merely by the appearance of the membrane, pick out the cases that had received antitoxin within the preceding forty-eight hours. In no case had the membrane reformed to any extent, and in no instance had there been any serious consequences from the use of the antitoxin. In a few cases in which abscess had occurred, cultures showed a pure growth of streptococcus. Urticaria had occurred in a considerable proportion of the cases, and there had been occasional eruptions, closely resembling either measles or scarlet fever. The local treatment had consisted in irrigations with hot saline solutions. An analysis of 83 cases in which the urine had been examined, both before and after the use of antitoxin, showed the urine free from albumin in 38, a diminution in the albumin in 11, and an increase in 4. In the cases subjected to early treatment, paralysis rarely occurred, but in those coming under observation at a late stage of the disease, paralysis had been observed in a large proportion of cases. In a very large proportion of the cases of diphtheria, the fatal issue was directly due to broncho-pneumonia.

Henry Jackson, M.D., of Boston, read a paper entitled

treatment of diseases other than diphtheria by antitoxins.

He said that as yet the composition of antitoxin was not definitely known.

In 1893 Klempe reported six cases in which he had tried upon the human subject, for the relief of pneumonia, injections of the pneumococcus, and, he thought, with fairly good results. So far, however, no practical benefit has been derived from this line of treatment. Theoretically, we ought not to expect to cure a lung, already diseased, by injections of this character; all that we ought to hope for would be the prevention of further extension of the disease process.

Regarding tetanus, it was to be noted that clinically it was most commonly found in injuries to the extremities 84 per cent. in a series of 395 cases. In 1885, Nicolai had found that garden earth produced this disease, and in 1886 Rosenbach succeeded in producing tetanus in the lower animals by injecting them with flesh from a person ill with the disease. He also described the bacillus, although he did not succeed in getting it pure. As the tetanus bacilli grow by spore formation, it is difficult to kill them. It should be remembered, however, that while they resist the action of strong chemicals, they are destroyed by boiling for five minutes. In 1890, Behring and Kitasato (?) published an article on the immunity of man and animals from tetanus by the use of injections, claiming not only to be able to produce immunity, but to cure one already affected with the disease. Other observers, however, had failed to confirm these claims made by Behring as to the *curative* property of the serum. An analysis, the speaker said, had been attempted in the case of this

antitoxin, with the following results: (1) It is an albuminoid body, being destroyed by a temperature of 68° C., but not affected by a temperature of 60° C.; (2) it cannot be dialyzed; (3) mineral acids destroy it, and (4) when dried *in vacuo*, it retains the original properties of the serum.

A study of a large number of cases gives a mortality of 80 to 90 per cent. in the acute, and 50 per cent. in the chronic form. The longer the duration of the disease after the onset of the symptoms, the better the prognosis. So far as he had been able to ascertain, the antitoxin had been used in 44 cases, in 40 of which the disease had followed injuries to the extremities. The mortality was 36 per cent. Of the 27 cases that recovered, the period of incubation in more than half of them was between the fifth and fifteenth day. One case was referred to in which the symptoms had been very slow in developing—not until the nineteenth day. When they did develop, however, they were terribly severe. Gibier's tetanus antitoxin was then injected, and with such marked benefit as to make it incumbent upon the physician to give this treatment a trial in every case of tetanus.

Extensive experiments, Dr. Jackson said, had been carried on by Marmorek with the antistreptococcus serum. He claims that the injection of a daily dose of ten cc. of the serum causes both general and local improvement, and a fall of temperature. The compound serum—that of horses immunized both for diphtheria and the streptococcus—was also said to yield good results. The general consensus of opinion, however, regarding the use of the antistreptococcus serum in puerperal cases was against its use, the mortality being 42 per cent.

Marmorek had treated 96 cases of scarlatina with the antistreptococcus serum, using a serum of 1–30,000, and giving it in doses of 10 cc. Ten of the cases were complicated with diphtheria, and were treated with the double, or compound serum. Nineteen of the cases had enlarged glands, but in not a single case did suppuration occur. On the other hand, it should be noted that Baginsky had treated 48 cases, in several of which the enlarged glands suppurated. His mortality in these cases was 14 per cent. as against a previous mortality of 22 to 30 per cent. Dr. Jackson said that he had found that in 646 cases of scarlet fever at the Boston City Hospital, the mortality was about 9 per cent.

It was natural, he said, that in a diseases like pulmonary tuberculosis, serumtherapy should be tried; for pathologists tell us that in 20 to 25 per cent. of autopsies on cases not known to be tubercular, cicatrices or cheesy deposits are found demonstrating a healed tuberculosis. Improvement had been reported in tuberculosis from serum injections, but it was much the same story as had been told so many times before in connection with the many new methods of treating this disease.

Le Grand had reported an epidemic of 40 cases of typhus fever in a prison with 12 deaths. Recourse was then had to serumtherapy, the serum being taken from those who had just recovered from the disease. Only one of the 39 cases so treated, died. Following the use of the serum, it was noted that there was a fall of temperature, an improvement in the pulse and a diminution in the coma.

One case had been reported in which there had been rapid recovery from a cerebrospinal meningitis after the injection of serum taken from a sister of the patient, who had just recovered from the disease.

Dr. H. C. Ernst of Boston, in opening the discussion, referred to various important and comparatively little known properties of the blood-serum. He said that its globucidal power—*i.e.*, its power to destroy blood-globules—had been especially made use of by the opponents of antitoxin, claiming that this was one of the possible causes of the disastrous results which they thought were attributable to the use of the antitoxic serum. Other properties of the blood-serum needing further study were its attenuating power, its coagulating power, and its toxic power. Its antitoxic power was, so far as now known, the most important of all. Behring had been led to look into this particular feature by the vitality of the bacteria at the point of inoculation, when injected into animals immune to these bacilli, For example, if the anthrax bacilli were injected into a person immune to anthrax, the germs would continue to grow and still there would be no symptoms of anthrax. This suggested the belief that it was not the bacteria but their tonic products, which were the active cause of such diseases.

Dr. Ernst said that the exactitude and accuracy of the laboratory experiments upon which the diphtheria antitoxin treatment were founded, had been demonstrated again and again. The clinical evidence of its value had just been fully presented by Dr. McCollom. He would present the following additional statistics: He had received reports from 181 cases, outside of the Boston City Hospital, with 15 deaths, or a mortality of only 8.2 per cent. In 346 other cases, doses of 3 to 5 cc. of antitoxin were used for immunizing purposes. Of this number there was no case of albuminuria or paralysis, and no severe or permanent symptoms had developed. This would seem to show conclusively that antitoxin is not harmful. He would conclude, therefore, that in the hands of a competent person, antitoxin, when properly prepared and properly administered, was of the greatest value in the treatment of diphtheria. Much had been published, more particularly in the daily papers, regarding the position taken by Dr. Winters of New York, in regard to this treatment. The speaker said that he had very recently had the pleasure of listening to a discussion on this subject in New York, and all that he need say was that all of Dr. Winters' colleagues, who had seen the same cases as he, had avowed their belief in the antitoxin treatment. It appeared at that meeting that Dr. Winters' arguments were largely based upon a misinterpretation of facts.

Dr. T. M. Rotch of Boston, said that in a large number of cases, collected from private practice by the American Pediatric Society, an equally low death-rate to that given to-day, had been reported as following the antitoxin treatment.

Dr. W. T. Porter of Boston, in presenting a paper on

INTERNAL SECRETION OF GLANDS,

Said that a modern definition of a gland was one or more epithelial cells, opening on one side into a cavity, into which the secretion of the cells is discharged. Such a definition would include both the uni-cellular glands of the alimentary canal and respiratory tract, and the so-called ductless glands—*e.g.*, the thyroid. But this definition does not include all glands. Certain cells extrude their products directly in the lymphatics, as for example, the hepatic cells, which convey glycogen and urea directly to the lymph channels. The term "internal secretion" should be confined to the manufacture of all secretory products which enter the lymphatics and blood, including not only those passing directly from the mother gland into the surrounding liquid, but all those resorbed from the gland cavities. The reader of the paper then referred to recent observations on pancreatic diabetes. It had been found, he said, that diabetes was due to the failure of an hitherto unknown function of the pancreas—*i.e.*, the using up of part of the sugar in the blood. He said that in 1882, Reverdin had first called attention to the peculiar cachexia following the removal of the thyroid gland from the human subject, and the marked effect upon the general health, upon the speech, and even upon the intellection. In 1885, Horsley had produced myedema experimentally by removing the thyroid from the monkey. It had also been found that the total removal of the suprarenals causes death, but that this might be averted by leaving a small portion.

Regarding the internal secretion of the testis, the speaker said that the assertions of Brown-Sequard, regarding the virtues of the testicular extract, had been since confirmed by other observers. Perhaps not the least remarkable facts in connection with the subject of internal secretion of glands were those illustrated by experiments in transplanting the thyroid and the pancreas to any part of the body where a proper vascular supply could be maintained, without producing the disastrous results well known to follow the entire removal of these glands.

R. C. Cabot, M.D., of Boston, read a paper upon

CLINICAL USE OF PREPARATIONS FROM THE THYROID PITUITARY BODY, SUPRA-RENAL CAPSULE, AND BONE-MARROW.

(To appear in an early issue of Medical News.)

Dr. H. P. Bowditch of Boston, said he saw no reason why extracts of glands should not be as likely to be beneficial as an extract from a nut, or a root or a leaf. He was inclined to think that they would play an important part in the therapeutics of the future. He had tried pancreatic extracts in a number of cases of diabetes, but with absolutely negative results.

It was arranged that the Surgical Section should present a series of five-minute papers setting forth the present aspect of orthopedic surgery. Twelve papers were then read by as many different members.

(To be continued.)

REVIEWS.

Occasional Papers on Medical Subjects. By Dr. W. Hawship Dickinson, Longmans, Green & Co., London, New York, and Bombay; 1896.

This volume of 250 pages is made up in great part of opuscles that have appeared in medical journals during the past forty years, a period covering the active professional life of one who has made his name honorably known in medical literature. The diversity of topics discussed and the catholicity of the writer is shown by a glance at the table of contents, which includes among the seventeen subjects treated such widely different subjects as the "Action of Digitalis on the Uterus," the "Changes in the Nervous System which Follow the Amputation of Limbs," the "Pathology of Chorea;" "Chorea, with Reference to its Supposed Origin in Embolism," an article which has been referred to so frequently, that it has become somewhat of a classic; "Hereditary Albuminuria," "The Morbid Effects of Alcohol, as Shown in Persons Who Trade in Liquor," and finally, a pleasant reminiscent article entitled "The Practice of Medicine at St. George's Hospital Forty Years Ago." In the last-mentioned article, Dr. Dickinson is at his best, both in point of style and handling of his subject. His protracted and intimate connection with St. George's Hospital, first as clinical clerk, then as physician, and now as consulting physician, has given him opportunity to be realistic in a charming manner, by contrasting the state of medical practice in the early part of the century with the conditions existing to-day, which are portrayed in many of the articles in the volume.

Some of his remarks indicate how completely the pendulum has swung from therapy to diagnosis, such for instance as when discussing the clinical records made by the great Thomas Young, whom he eulogizes by referring to as "the most comprehensive genius and greatest man of science who ever held the office of physician to St. George's or any other hospital;" he says, "these notes are ample and minute in treatment, but without any clinical features except an occasional word of diagnosis, and here and there a brief note of *post-mortem* appearances. Pithily expressed, the treatment of disease has advanced in the last forty years, not so much in the direction of what to do as what not to do. And then what a volume of truth and honest expression of experience is summed up in the words "We trust nature more—we have learned the use of potassium iodid."

Of the many articles in the volume of permanent scientific importance, two in particular may be mentioned, "A Lecture on the Cardio-vascular Changes of Renal Disease, with Some Observations on the Large Arteries," which appeared originally in the *Lancet* of July 20, 1895, and on the "Presystolic Murmur Falsely So-called." In the latter, the author ably contends against the origin of a murmur in auricular contraction, the theory of Fauvel, which was so earnestly advocated by Gairdner in Great Britain, but which now has few believers.

Some of the papers have a historical interest, especially that on the "Action of Digitalis on the Uterus," and on the

"Pathology of Chorea," but each one of the articles sustains the liveliest interest, and is profitable, suggestive reading. It is a pleasure to recommend a medical book in which dogmatic and dictatorial statements are consigned to the background, and the plain statement of a ripe experience is put to the fore.

URIC ACID AS A FACTOR IN THE CAUSATION OF DISEASE. A CONTRIBUTION TO THE PATHOLOGY OF HIGH ARTERIAL TENSION, HEADACHE, EPILEPSY, MENTAL DEPRESSION, PAROXYSMAL HEMOGLOBINURIA AND ANEMIA, BRIGHT'S DISEASE, DIABETES, GOUT, RHEUMATISM, AND OTHER DISORDERS. By ALEXANDER HAIG, M.A., M.D., Oxon., F.R.C.P., etc. Third edition, with 54 illustrations. Philadelphia: P. Blakiston, Son & Co., 1896.

IN this volume of 600 pages, the author has practically republished and amended his former writings on the influence of uric acid as a factor in the causation of disease. To the rather formidable list of diseases mentioned on the title page, Raynaud's disease, hysteria, and asthma might be added, and the list would be quite complete. If the reader will always bear in mind that uric acid is *a* factor, and not *the* factor, such a book as this will do no harm; but we fear, with all due deference to Dr. Haig's extensive researches, that he is trying to prove too much, and that the relative worth of other etiological factors (in epilepsy and hysteria, for instance) will be underrated in consequence of his insistence on uric acid. To take epilepsy, again, a certain coterie of medical men hold that epilepsy is due chiefly to eye-strain. Haig says uric acid is the powerful provocative agent in the functional cases. Which one is it, or is it neither? A change in the amount of uric acid excreted does not prove the case, particularly since it is still doubtful whether the excess of uric acid in the blood is the cause, or the result of, an epileptic seizure.

A single paragraph from the chapter on Raynaud's disease will show Haig's general method of argumentation. To say that it is a trifle vague, is to put it mildly. This paragraph reads:

"The fact is, that in uricacidemia the vessels all over the body are obstructed, and all the most important organs and tissues give evidence that their functions are thereby disturbed; and the relation between Raynaud's disease and certain neuroses, such as hysteria, epilepsy, and the headache and mental depression of which I have spoken, amounts simply to this: that they are all effects of uricacidemia, and for this reason often occur together, and these disturbances . . . merely prove that the disturbance of circulation which produces the gangrene in the extremities produces also such changes in the intracranial circulation that certain contemporaneous changes in the functions of the great nerve-centers result."

Has it ever occurred to Dr. Haig to inquire, if his reasoning be correct, why Raynaud's disease is not a very common affection in those having epilepsy, hysteria, or migraine?

We have no intention of speaking disparagingly of Haig's researches. His facts may be well-founded, though some of them have been opposed by Herter and others, but the inferences drawn therefrom are hazardous. The author attempts to prove too much. He has done good work, however, in calling the attention of the profession to the importance of uric acid as an etiological factor in many diseases; and to those who wish to know all that can be said in favor of uric acid, this book will be welcome.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 20, 1896.

June 12th.—Surgeon R. WHITING, detached from the "Monterey," ordered home and granted three months' leave.

Surgeon C. T. HIBBETT, detached from the "Bennington" and ordered to the "Independence."

Surgeon H. T. PERCY, detached from the Board of Examiners, Washington, D. C., July 1st, and ordered to the "Monterey."

Surgeon W. A. MCCLURG, ordered as member of Medical Examining Board, Washington, D. C.

Passed Assistant Surgeon J. W. BAKER, detached from Board of Examiners, New York, June 22d, and ordered to the "Bennington."

Passed Assistant Surgeon C. F. STOKES, ordered as recorder of Medical Examining Board, New York, June 22d.

June 13th.—Surgeon A. C. RUSSELL, detached from Board of Medical Examiners, New York, July 5th, and granted leave until August 7th, with permission to go abroad.

Assistant Surgeon M. K. JOHNSON, detached from the "Franklin" and ordered to the "New York."

Assistant Surgeon F. C. COOK, detached from the "New York" and ordered to treatment at Naval Hospital, New York.

June 15th.—Assistant Surgeons W. N. WHEELER and R. S. BAKEMAN, ordered to instruction at naval laboratory, New York.

Passed Assistant Surgeon J. W. BAKER, ordered to delay reporting until July 18th.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 27, 1896.

June 23d.—Assistant Surgeon S. B. PALMER, detached from the New York Laboratory, June 29th.

June 26th.—Passed Assistant Surgeon GEO. ROTHGANGER, detached from the "Independence," July 15th, and ordered to the "Oregon."

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE TWENTY DAYS ENDING JUNE 20, 1896.

MCINTOSH, W. P., Passed Assistant Surgeon, to proceed from Louisville, Ky., to Cincinnati, Ohio, to inspect unserviceable property; then to rejoin station, June 13, 1896.

PERRY, J. C., Passed Assistant Surgeon, granted leave of absence for twenty days, June 20, 1896.

GARDNER, C. H., Assistant Surgeon, order of May 27, 1896, directing him to report for examination revoked June 5, 1896.

BLUE RUPERT, Assistant Surgeon, to proceed from San Francisco, Cal., to Angel Island Quarantine Station for duty, June 18, 1896.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 2, 1896, TO JUNE 22, 1896.

Captain Louis A. LaGarde, Assistant Surgeon, U. S. Army, is granted leave of absence for one month.

Captain Philip G. Wales, Assistant Surgeon, is relieved from temporary duty at Fort Monroe, Va., and will return to his proper station, Fort McPherson, Ga.

Leave of absence for one month, with permission to apply for an extension of one month, is granted Captain W. Fitzhugh Carter, Assistant Surgeon.

VOL. LXIX. NEW YORK, SATURDAY, JULY 25, 1896. No. 4.

ORIGINAL ARTICLES.

SUSCEPTIBILITY AND IMMUNITY, WITH SPECIAL REFERENCE TO SURGICAL CASES.[1]

BY ROSWELL PARK, A.M., M.D.,
OF BUFFALO, N. Y.;
PROFESSOR OF SURGERY, MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO.

THE following remarks upon the topic of immunity and susceptibility, relating especially to surgical cases, are the outcome of a direct request by the Business Committee of the Association to prepare a paper upon this subject. It certainly is a topic which should earnestly engage the attention of all surgeons. Indeed, the subject is one of fundamental importance, since the conditions which predispose to infection or enhance resistance to it are matters of the greatest interest to every operating surgeon, and should be taken into account in weighing the advisability of all grave emergency operations.

I prefer to approach the subject first from the side of immunity, which may be spoken of (1) as local and general; (2) as congenital or acquired; and, (3) as absolute and relative, according to the light in which we consider the question.

First of all, man seems to be immune from numerous infections which are common to many of the domestic animals—for instance, hog cholera, symptomatic anthrax, and chicken cholera; while he is in common with them susceptible to the infection of anthrax, glanders, tuberculosis and actinomycosis. Secondly, men differ very much among themselves in susceptibility to the same disease. This is particularly true with regard the exanthems, smallpox, cholera, and influenza. A goodly percentage of mankind escape scarlet fever, though repeatedly exposed; and I have often seen children who have never had it exposed to measles, and yet without contagion. Of course we explain this, so far as mere words can, by saying that at the time of exposure their bodies were not receptive or were resistant; all of which is a statement of apparent fact, but no explanation whatever.

We see many similar differences among animals, or at least we have many analogous instances. Birds suffer in nowise from belladonna nor opium, nor do goats from nicotin. The hedgehog is perfectly immune to the bite of poisonous snakes. The freedom from bad results seen in the practice of veterinary surgeons is due to the relative immunity from infection of the animals upon which they operate, and one of the hardest lessons to teach young workers in the surgical laboratory is that they must not disregard the rules of antisepsis in human surgery as they do when experimenting and operating upon dogs.

Susceptibility seems, in fact, to be inseparable from a study of the causes which favor infection, which I would take up in the order following:

1. *The Virulence of the Infecting Organisms and the Amount Introduced.*—As between the various bacteria, there is the widest difference in the matter of virulence, and it is certainly true that even in the same species there are great differences under varying circumstances,—these depending upon conditions as yet incapable of exact statement. With some organisms it is enough to infect an animal with only one in order to bring about a fatal result. In the guinea-pig, for instance, a single virulent anthrax bacillus will produce death; whereas in more resistant animals many are required, and in those which are immune, no amount seems to disturb the life of the creature. Man is much more susceptible to pyogenic organisms than most of the lower animals. When several species are introduced at once, some of them develop and do harm, the others die; but the same results cannot be gotten with animals of different species. Mice are very susceptible to anthrax; rats, almost immune. Rabbits and mice are extremely susceptible to rabbit septicemia; guinea-pigs and rats, immune; also sparrows and pigeons. Spirilla of relapsing fever have only been successfully inoculated into apes. Leprosy, syphilis, and gonorrhea have never been transmitted to any of the lower animals.

The virulence of micro-organisms is itself affected by temperature, sunlight, moisture, dryness, as well as by association with other bacteria. Those which have been repeatedly passed through the animal body become more virulent than those cultivated for generations in laboratory test-tubes. Variable virulence is especially characteristic of

[1] Read before the American Surgical Association, at Detroit, Mich., May 27, 1896.

the cocci of erysipelas, the colon bacillus and the anthrax bacillus. The common bacillus prodigiosus is ordinarily held to be non-pathogenic, but its presence has a strange, often reinforcing, effect upon the virulence of certain other organisms, in some cases enhancing it, in others suppressing it. The natural immunity to anthrax of rabbits and pigeons can be overcome by injecting the prodigiosus at the same time. Roger has maintained that the prodigiosus produces a decomposition product which is soluble in glycerin and which produces a modifying action upon the animal organism. Moreover, by previously injecting substances which dissolve blood-corpuscles or affect their integrity,—for example, pyrogallol and hydracetin,—Gottstein has made guinea-pigs, which are ordinarily immune to chicken cholera, susceptible to the disease. So, too, white mice can be made susceptible to glanders, from which they are ordinarily exempt, by producing an artificial diabetes by adding a little phlorizin to their food. Anthrax has been communicated to immune animals by subjecting them to the influence of curare, chloral, and alcohol. This is particularly true of dogs, frogs, and pigeons.

Perhaps no better illustration of the combined effects of exciting and contributing causes can be found than the occurrence of pneumonia. The micrococcus lanceolatus is present in the salivary secretions of many individuals. Nevertheless, it acts as the infectious agent in producing croupous pneumonia only under peculiar circumstances, the most notable of which appears to be exposure to cold, bad hygienic surroundings being a secondary and contributing cause.

2. *Association.*—This, which has been already alluded to, deserves further consideration under a separate head. Under natural conditions, bacteria are seldom found in pure cultures, while by mutual association remarkable changes are produced, whose results are so strange and yet so contradictory, that no law governing them has as yet been formulated, it being necessary to establish each case by experimental investigation. One of the most remarkable illustrations is that of a combination of anthrax bacilli and erysipelas streptococci, each of which by itself is virulent; yet, when introduced together, they appear well-nigh harmless; the diplococcus of pneumonia, on the other hand, when combined with the same anthrax bacillus seems to have a greatly augmented power.

Very small doses of pure cultures of bacillus pyocyanus are fatal to rabbits if, at the same time, a considerable quantity of a filtered culture of the same bacillus is thrown into their veins. The animal can resist either alone, but the combination of the two is too much for it. The same is true of symptomatic anthrax. It is also true of old and attenuated cultures of the common pyogenic organisms, if at the same time a living culture of proteus vulgaris be introduced. This may shed not a little light upon the epidemics of typhoid fever among those who have a common water supply.

Some rather startling facts have been discovered incidentally to the study of immunity and infection. Thus, Roux found that the blood-serum of a horse which he immunized against tetanus neutralized the poison of the cobra, though the converse was not true; also that the blood-serum of a rabbit made immune against hydrophobia, will protect a susceptible animal against a dose of cobra poison five times as large as that ordinarily required to kill.

3. *Hereditary Influences.*—That immunity is transmitted from parent to offspring no one will dispute. Explanation of this fact is almost as remote as ever, but its recognition is of the greatest importance to practising surgeons. Liability to infection seems, to some extent at least, a feature of hereditary habit of tissues.

4. *Local Predisposition.* This is a also a factor of great importance. Once given a distinct infection, and hyperemia is often a contributing cause, due to inflammation. On the other hand, anemia of tissues seems sometimes to be a favoring condition. When dogs are freely bled, the pneumo-bacillus of Friedländer will affect them as ordinarily it will not do at all. In parts involved in chronic congestion, the blood flows more slowly, while vessels are dilated and susceptibility is apparently thereby increased. Infection here produces a type of disease often spoken of as hypostatic inflammation. General anemia is also a predisposing cause; while such toxemias as diabetes, etc., are still more so, the liability of diabetic patients to suppuration and gangrene being proverbial.

The presence of foreign bodies has also much to do with infection, since when bacteria and foreign bodies are introduced together, the presence of the latter will practically always excite suppuration, which would, without it, not occur. The withdrawal of trophic nerve influences also permits of infection, as is instanced by the ease with which bedsores form in paralytic patients. Obstruction to circulation or to escape of secretion, also easily permits infection, for example—in the appendix, the kidney, the gall-bladder, the sali-

vary ducts, etc. Furthermore, one may formulate a quite comprehensive statement, and say that all such lesions as solutions of continuity, hemorrhages, degenerations, vascular stasis, perforations, etc., increase more or less the liability to infection. The ease, for instance, with which the colon bacillus pierces the coats of an intestine which has been in the slightest degree disturbed or abraded is wonderful. They collect, for example, in the sac of a strangulated hernia, and even other organisms are often found. Hence the rule for careful disinfection of the sac and the exposed gut before returning the latter to the abdomen. In time past, it has been held that the presence of blood-clot within a wound was most undesirable, it being thought that it offered a favorable nidus for the development of bacteria. It has been more recently shown that virulent organisms injected into the blood-clots occasion no suppuration. Blood-clot, therefore, has of late been utilized in the healing of a certain class of wounds, and we now know that retained clot which produces no undue tension is not a common source of danger.

5. *Vestiges and disappearing organs and tissues.*—It is being more and more clearly established that those organs which are, in the course of ages, undergoing retrogade metamorphosis, or are disappearing, are especially liable to infection and inflammatory destruction. This is particularly true of the appendix, and is true as well of those collars of lymphoid tissue which surround almost all of the original outlets or inlets of the archetype embryo. We see it well illustrated, for instance, in the lymphoid tissue about the pharynx, the pharyngeal, faucial, and lingual tonsils. If it should prove true, though I hold it not yet to be completely demonstrated, that cancer is a parasitic condition, we shall have here a beautiful illustration of this fact, in that it is notorious that cancerous changes occur most often in localities just alluded to, as, for instance, the pylorus, the cecum, etc.[1] At all events, it seems to be largely true that lymphoid tissue is retrogressive in its tendency, and all such tissue is peculiarly susceptible to infection.

6. *Preëxisting Disease.*—Here must be reckoned, first, previous and long-existing toxemias, *e.g.*, scurvy, diabetis, syphilis, etc.; second, diathetic conditions, like lithemia, cholemia, acetonuria, and the various conditions represented by oxaluria, or those in which acetone, peptone, or excess of uric acid are found in the urine. It has been recently shown by the experiments of Pansini that the addition of uric acid as well as of glucose to blood-serum markedly diminishes its bactericidal activity. On the other hand, the injection of an alkali into the blood of a rabbit increases its resistance to anthrax, and enhances the bactericidal power of its blood-serum. Third, the immediate or recent results of other acute diseases, as, for instance, tuberculosis following quickly upon measles. Recent toxemias have, in fact, an important bearing for us, inasmuch as after typhoid or other acute wasting disease, including the exanthemata, surgical operations are sometimes followed by a failure of tissues to heal, and should consequently be postponed until after complete recovery, save in cases of emergency. The puerperal state is also one in which operations are to be avoided, if possible. But, above all the ordinary expressions of recent toxemia is to be placed that somewhat vague or varying condition which I like to call enterosepsis, or intestinal toxemia, which has been spoken of in time past as fecal anemia, stercoremia, copremia, etc., as one whose existence makes positively dangerous the performance of operations of any kind, since it certainly predisposes to septic disturbance. It is a condition of chronic intoxication in more or less mild degree, in which state no wise surgeon likes to operate unless compelled. I would wish, also, to place much more stress upon a still somewhat vague condition, ordinarily spoken of as lithemia, characterized by hyperacidity of, and often by crystals of oxalates in the urine, as one which should always be corrected, if time be given, before any serious operation. Of itself it is serious, since it often leads to the auto-intoxication just spoken of, from the intestinal canal; and the two together constitute a condition which is quite likely to baffle the surgeon's best efforts.

There are also to be taken into consideration the anatomical changes peculiar to the various ages; for example, the arterial scleroses of old age, with their accompanying cardiac debility and other tissue alterations, which favor sluggishness of repair, and lead not infrequently to

[1] If we are to regard cancer as an infection, cancer mortality is lowest where the struggle for existence is hardest and the density of population greatest, and the tubercular mortality the highest; while among the wealthy, where the standard of health is better and life is taken easier, and among the fast, cancer mortality is highest. According to Williams, there are no more potent factors in the causation of cancer than high feeding and fast living. Cancer is twice as frequent among the whites as among the blacks, it being notorious that negresses rarely suffer from uterine or mammary cancer. On the other hand, they are very prone to uterine fibroids. Cancerous diseases are almost or quite unknown among the negroes, even in their native country. Williams states that this immunity applies alike to meat-eating and vegetarian savages. On the other hand, cancerous diseases are very prevalent in all highly civilized communities. The proportion of cancer among dark-complexioned whites is lower than in the light-complexioned—in the proportion, according to some statistics of 69 to 31.

sloughing or to bedsores. Amyloid changes also betoken impaired vitality. Nursing infants, while apparently exempt from many of the infectious diseases, possess relatively small power of resistance to surgical operations. General anemia and impaired body nutrition predispose to most infections, and acute starvation notoriously so.

7. *Personal habits and environment.*—Diet has much to do with tissue resistance. Rats fed on bread are more susceptible to anthrax than those fed on meat. Hunger makes pigeons highly susceptible to the same disease, and artificial immunity induced in various animals is quickly destroyed by starvation. Prolonged thirst seems to have the same result. Fatigue notoriously reduces immunity, either in animals or men. This is abundantly shown upon the former in various laboratory experiments, and in the latter instance by the accumulated experience of centuries. Drugs or foods which impair the vitality of the red corpuscles reduce immunity; and even by the injection of water into the circulation, the germicidal power of the blood may be reduced. If this be so, one may better appreciate the effect of the various toxemias alluded to above, which proceed from the intestine or from the genito-urinary tract. Climate has not a little to do, as have also extremes of weather, in influencing resistance to infection, or recovery after serious operations. Pasteur has shown that fowls, which are naturally immune to anthrax, become infected when subjected to artificial refrigeration after inoculations. Dark habitations, poorly ventilated, constitute surroundings which notoriously predispose. Rabbits inoculated with tuberculosis and confined within a dark, badly ventilated cell, die, while others similarly inoculated and allowed to roam at large, present but slight evidences of the trouble. Certain occupations predispose. This is preëminently the case, for example, with workers in mother-in-pearl, who are exceedingly liable to a peculiar form of osteomyelitis; while the peculiar effects of phosphorus and mercury in producing necrosis are classical. It is important also to remember that the prolonged necrosis of these drug intoxications may produce such changes in the blood and tissues that vital processes of repair, cell resistance and chemiotaxis may be so far interfered with as to facilitate subsequent infection. This, too, may be at least the possible effect of certain antiseptic agents, which, used in too great strength, interfere with normal reactions and lead to decomposition, either of drugs or of vital fluids, by whose products harm may be done.

Finally, the influence of local injury to tissues, particularly of contusions, which cause tissues to lose their vitality, is a thing to be strenuously insisted upon as predisposing to infection. Both in clinical experience as in experimental investigation, it is every day shown that tissues which ordinarily resist infection succumb to inoculation after bruising or the ligature *en masse.*

8. *Fetal infection.*—In only a very limited class of cases may infection be transmitted from mother to fetus. But when this can occur the surgeon is often deeply concerned. While syphilis is the only infection capable of direct transmission through the ovum or spermatozoön, intrauterine infection may yet occur, since the placenta is not a perfect filter, but is occasionally passable by microörganisms. It may be made pervious, either by pre-existing lesions or by virulence and activity of the bacteria. In animals, for instance, the bacilli of chicken cholera and of symptomatic anthrax, as well as even the pyogenic cocci, can traverse this barrier. In mankind, infection has been observed *in utero* in smallpox, measles, scarlatina, relapsing fever, syphilis, tuberculosis, croupous pneumonia, typhoid fever, anthrax, and common septic infection.

Conditions which afford protection or immunity.—Immunity may also be (*a*) local or constitutional; (*b*) congenital or acquired; and (*c*) may concern some particular infection, or amount to a general protection. Immunity for a particular infectious disease is often conferred by one attack. This is, for the most part, true of the exanthemata, yellow fever, etc. It is not true, however, of tuberculosis, nor the so-called surgical infections; neither is it true of septic infection, *e.g.*, septicemia, etc. It is true in only very modified degree of diphtheria.

Immunity is in some sense a racial characteristic, as, for example, in the case of the Japanese, who, it is said, never have scarlet fever; and of the negroes, who escape yellow fever. The essential characteristic, however, which makes the negro immune against yellow fever does not protect him against tetanus, to which he is unusually susceptible. Negroes are less liable to malaria and dysentery than are Europeans. Japanese are more susceptible to beriberi than are Europeans.

Acquired immunity may be *natural* or *artificial;* natural in the instances above-mentioned, artificial when produced by inoculation with attenuated bacteria, or by the injection of certain chemical substances, or by change of environment, or by modification of food or by drugs. The most effective, the most prompt, and the most measurable

effects, are produced either by inoculation with bacteria of attenuated virulence, by injection of sterilized cultures, by employment of blood-serum, or of some antitoxin separated and concentrated from it, taken from animals rendered immune by one of these methods. It should be emphasized that serum, or its preparations, used for this purpose, deserves more than the term "protective" often applied to it. It is often, in effect, a *healing* serum, since it does more than protect against the disease—it usually helps to cure it while in its active stage. The question of how serum produces immunity, of absorbing interest as it is, is not one to be discussed in this place; neither is the question concerning the origin of the immunizing substance, be it what it may. Acquired immunity is not necessarily a matter of juggling with bacteria of the disease in question, but may be produced by the employment of others. Of interest, also, is it to state that individuals or animals possessing a natural immunity against a given disease, have in their blood-serum no immunizing substance as against that disease. This substance is only to be produced by an artificial immunization.

In a general way, it may be said that the conditions which afford protection, so far as they are controllable by the surgeon, are those which tend to increase what, for lack of better knowledge, we must call vital resistance, and to decrease vulnerability. The ideal condition is that which is summed up in the generally received expression of "perfect health," in which the various secretions and fluids, possessing their normal acidity or alkalinity, are sufficient to destroy or render inert harmful organisms entering their precincts. Where there is perfect equilibrium between ingestion and excretion, which shall permit no extravascular excitement, no congestion, no exudate which may become infected—in other words, where the natural functions are performed in an ideal manner—under these circumstances almost any accident may be survived and repaired without perceptible struggle, the tissues and fluids in their healthy state being abundantly able to dispose of such bacteria as may accidentally enter. Traumatic exudates are now absorbed, and speedily; the hyperemia of irritation is quickly compensated for; while here we find those general conditions which surgeons everywhere rejoice to see, and under which they feel warranted in making any necessary interference. Here, too, should infection by accident occur, as by the introduction of a foreign body, phagocytosis is so prompt and filtration through lymph nodes so thorough, that the worst which may happen is local suppuration. This general condition is met with in its most complete expressions where no hereditary influences have conspired to dwarf organs or impair their activity; where no poison, like that of syphilis, or uric acid, or alcohol, interferes with perfect nutrition and normal cell activity; where exposure has not lowered tissue vitality; where starvation and fatigue have not conspired to temporarily reduce it; and where mental worry has not lent its aid in contributing to impair normal processes. These, then, are the conditions which afford protection and under which the surgeon loves to work.

The conclusions of surgical importance which may be legitimately reached from the study of the conditions dealt with in this paper, are essentially these: That the surgeon in emergency cases has to do the best he can, not merely with the means at hand, but with the tissues at hand; and here, so long as he can control what may happen outside of the body, he has done his full moral and legal duty. On the other hand, in any case where patients deliberately come under observation, and where time may be afforded, it is the surgeon's bounden duty,—bearing in mind a summary of the conditions which notoriously conspire, upon the one hand, to lower vulnerability, upon the other hand, to afford protection,—to so order the habits, the diet, the surroundings and the preparation of his patient, as to restore his tissues and vital fluids, so far as possible, to their normal condition, before he interferes with their functions by an operation.

A distinct and as yet an unworked field lies before him who will study carefully and for sufficient length of time the effect of anesthetics in increasing susceptibility and infection. This is a problem which must be worked out rather upon human patients than upon animals, since the conditions are so exceedingly different, most of the animals used for experiment being too relatively insusceptible, dogs notoriously so. I have for years cherished the opinion that anesthetics affect all people to a greater or less degree in this direction; yet am not able to present to you any definite statistics or statements, Loss of blood is certainly a factor lowering vitality; and in that complex condition of shock, it must assuredly be that natural immunity is at least temporarily lowered. Equally important in my estimation are the auto-intoxications and toxemias, of which two particularly call for mention here. The effect of sugar in the urine, or, rather, the effect of the condition which leads to its presence, is everywhere recognized; but I am more and more

convinced that in the body condition which is most easily recognized by hyperacidity of urine, and which is so often a complication of uricacidemia, oxaluria, etc., we have a grave and sometimes insuperable obstacle to ideal success after operating. The other condition to which I particularly allude, is that which I usually speak of as intestinal toxemia, and relates to auto-intoxication produced by absorption from the contents of the alimentary canal of substances which ought not to be therein retained, nor allowed to so accumulate nor undergo chemical changes which shall permit such absorption. This condition is, in large measure, represented by chronic constipation; and yet it certainly does occur in patients who have a regular daily habit of alvine evacuation. It is to be recognized by the hue of the skin, by the appearance of the tongue, often by the presence of indol or indican and ethereal sulphates in the urine, and quite often by the diminished elimination of the fluid and mineral elements of this fluid. It should be combated, if possible, by a careful course of hot-air or Turkish baths, copious draughts of fluid, the administration of saline laxatives and of intestinal antiseptics, among which in my estimation the very best is a solution of mercury and arsenic in hydrocholoric acid, given in the shape of mercuric chlorid, dissolved in dilute muriatic or nitromuriatic acid, with the addition of liquor arsenici chloridi. I have tried a great variety of the vaunted intestinal antiseptics, but have settled upon the conviction that some such mixture as this gives results far superior to any which can be obtained from salol, naphthalin, etc. If, in conjunction with these measures, we resort to exercise, when it can be taken, to sunlight, which is always available, and perhaps to massage, by which circulation is quickened and equalized, excretion hastened, and waste material dislodged and taken out of the system, we have done what we can to prevent infection.

I have, furthermore, for years, contended that since the inauguration of the so-called antiseptic era, in our enthusiasm for combating infection from without, we have lost sight of, and, to a great extent, neglected a most important truth, which we cannot afford to disregard, namely, the importance of recognition and the successful prevention of infection from within. Certain it is that in the majority of instances the latter (*i.e.*, infection from within) is much the more liable to ensue, and particularly in a class of cases where one is tempted, for one reason or another, to be less careful than he ought to be. I would give, then, this most important practical conclusion to my remarks, that only he who weighs judiciously the possibility or the imminent probability of one or the other of these forms of infection is really capable of guarding against both of them, and that the best surgeon is he who will always take time, when it can be afforded, for the preparation of his patient for operation. In other words, I would remind you of Sir James Paget's too often neglected statement, that we ought to examine patients for operation with fully as much care as we do for life insurance; and add to it, that if this examination be so conducted we shall often find that which will make us hesitate and prepare them, before subjecting them to the enhanced risk of what may, in other respects, seem for their good.

INTUBATION OF THE LARYNX IN DIPHTHERIA, WITH REPORT OF TWENTY-FIVE CASES.

By MELVIN M. FRANKLIN, M.D.,
OF PHILADELPHIA;
SURGEON TO THE CHARITY HOSPITAL.

This subject has been so exhaustively written upon during the past few years that it is with some little hesitancy I report the following cases, directing attention to a few points worthy of special mention. The following is a resume of a number of cases of intubation performed by me during the past year. Success in intubation depends upon the following conditions: (1) the time at which the operation is performed; (2) the degree of toxemia existing; (3) the treatment following the introduction of the tube.

In consideration of the first condition regarding the time of the operation, it may be said that each case is a law unto itself, but a few general principles that have guided me in my cases are as follows: If there be any membrane in the fauces, or if a history of diphtheritic infection and dyspnea, due to laryngeal stenosis, appears, the sooner the tube is introduced the better for the patient, because of the great difficulty of perfectly oxygenated blood in coping with the overpowering influences wielded by the toxins of the Klebs-Loeffler (diphtheria) bacillus. There is a still greater difficulty when imperfectly oxygenated blood has to accomplish the same result, not to mention the demoralizing effect caused by the muscular fatigue of forced respiration; and lastly, the untoward results produced by a plus quantity of CO_2 in the blood.

The degree of toxemia existing prior to or at the time tubage is performed varies greatly with each case. It does not necessarily depend upon

No.	Sex.	Age.	Duration before intubation of larynx. Laryngeal Symptoms	Duration before intubation of larynx. Pharyngeal Symptoms.	Time Tube Worn.	Complications.	Result
1	M	13 mo.	12 hrs.	24 hrs.	Tube introduced and allowed to remain 6½ days—withdrawn and after a period of 3 hours reintroduced and left in six days; withdrawn and after 5 hours was again introduced, remaining 4½ days.	Paralysis of the muscles of respiration.	Recovery
2	F	2 yrs. 8 mo.	6 hrs.	12 hrs.	5 days.	Nephritis.	Recovery
3	M	4 yrs.	10 hrs.	36 hrs.	6 days.	.....	Recovery
4	F	7 yrs.	4 days.	5 days.	12½ hours.	Paralysis of heart.	Death
5	F	3 yrs. 5 mo.	4 hrs.	2 days.	Tube in 5 days, after 8 hours reinserted for 6 days.	Nephritis.	Recovery
6	M	2 yrs.	8 hrs.	3 days.	Tube in 5 days, after 10 hours reintroduced for 6 days.	.....	Recovery
7	M	3 yrs. 8 mo.	4 hrs.	2 days.	Tube in 5 days, after 4 hours reintroduced for 4 days.	.....	Recovery
8	F	4 yrs.	12 hrs.	1 day.	Tube in 4 days.	Nephritis.	Recovery
9	M	7 yrs.	2 days.	3 days.	Tube in 3½ days.	.....	Recovery
10	M	2 yrs. 3 mo.	24 hrs.	4 days.	Tube in 6 days.	In this case there was no membrane visible in fauces, but as stenosis was marked, although the diagnosis of diphtheria was questionable, a tube was introduced. At the end of 6 days tube extracted, and followed by *paralysis of lower extremities.*	Recovery
11	M	16 mo.	12 hrs.	2 days.	Tube in 5 days, after 3 hours reinserted for 4½ days.	Severe diarrhea.	Recovery
12	M	6 yrs.	2 days.	2 days.	Tube in 24 hours.	Pneumonia at time of tubage.	Death
13	M	5 yrs.	12 hrs.	3 days.	Tube in 4 days.	Nephritis.	Recovery
14	F	4 yrs.	10 hrs.	2 days.	Tube in 6 days.	.....	Recovery
15	M	2 yrs. 11 mo.	12 hrs.	24 hrs.	Tube in 24 hours, coughed out and larger size introduced for 5 days.	.....	Recovery
16	F	1 yr. 7 mo.	8 hrs.	2 days.	Tube in 3 days, after 18 hours reintroduced for 4 days.	.....	Recovery
17	F	3 yrs. 4 mo.	22 hrs.	3 days.	Tube in 5 days, after 1½ hours reintroduced for 6 days.	.....	Recovery
18	F	2 yrs. 1 mo.	4 days.	5 days.	Tube in 18 hours.	Paralysis of heart. Refused nourishment and tube extracted.	Death
19	M	11 yrs.	1 day.	3 days.	Tube in 2½ days.	Paralysis of constriction of pharynx.	Recovery
20	F	4 yrs. 7 mo.	12 hrs.	2½ days.	Tube in 6 days.	Nephritis.	Recovery
21	F	6 yrs.	6 hrs.	24 hrs.	Tube in 5½ days.	Paralysis of constriction of pharynx.	Recovery
22	M	4 yrs.	24 hrs.	3 days.	Tube in 5 days, after 6 hours reintroduced for 5 days.	.....	Recovery
23	M	8 yrs.	2 days.	2 days.	Tube in 6 days.	.....	Recovery
24	F	3 yrs. 6 mo.	12 hrs.	4 days.	Tube in 5 days, after 12 hours reintroduced for 4 days.	Severe hemorrhage from nose.	Recovery
25	F	2 yrs. 7 mo.	12 hrs.	12 hrs.	Tube in 6½ days.	Nephritis.	Recovery

the amount of membrane visible at the point of infection—generally some part of the upper respiratory tract. The mildest cases, clinically, not to be diagnosed diphtheria, are sometimes followed by grave, if not fatal complications, as in one of the cases about to be reported where the respiratory functions were, for a time, practically abolished, only again to be restored by heroic therapeutic measures; and still another where there was no membrane at any time visible, yet followed by complete paralysis of the lower extremities. This is not an uncommon occurrence. Jacobi[1] states: "Thus there is no case of diphtheria—beyond, *perhaps*, those of the mild tonsillar form—but ought to make us anxious and afraid. Indeed, there is no safety and no positive prognosis until the patient is quite recovered, and even advanced beyond the period in which paralysis may develop."

The keynote of the situation lies practically in the treatment following the introduction of the tube. At this point a brief description of the technic and instruments required for the operation will not be amiss.

The instruments now almost universally used are those of O'Dwyer, the workings of which need not be here described. All that may be said is that it is better to use the old extractor rather than the later invention, which, to lessen the difficulty of extraction, causes a metal hook to be held on the tip of the index finger by a string attached to a ball held in the palm of the hand, but unfortunately necessitates a bridge of wire across the face of the tube. This method, though greatly lessening the difficulty of extraction, increases the likelihood of aspiration pneumonia by preventing the epiglottis from coming in as close contact with the face of the tube as it might if this were not the case.

In performing the operation of intubation the child is placed upon the lap of the nurse or assistant, wrapped in a blanket, and the arms secured by the nurse holding the elbows so as not to interfere with the respiratory movements.

The patient's head is secured by the assistant, and the position[2] "of the head and body should be as if he were hung from the top of the head," and this position should not be deviated from during the insertion of the tube.[3] The mouth-gag is then placed in position, and the operator standing directly in front of his patient, passes the left index finger down the side of the mouth over the posterior portion of the tongue, hugging closely the right lateral wall of the pharynx until he feels the glosso-epiglottic fold. The finger is then swept toward the median line. By this motion the epiglottis is thrown forward. The same finger is then slid slightly backward until the tip comes in contact with the rima-glottidis, the palmar surface of which holds the epiglottis firmly forward. The introducing instrument, holding the tube, is now passed down in the median line, swept over the posterior portion of the tongue, until the tip of the tube comes in contact with the finger. The handle of the instrument is then raised so as to prevent the tube being carried into the esophageal opening. The tube is then pushed into the larynx, the trigger is pressed forward, and the obturator released. Pressure should then be made upon the tube with the finger so as to sink it well into the larynx. As soon as the obturator is removed there is usually a violent respiratory effort, which is accompanied by a gush of mucus or membrane from the tube, after which the breathing is usually satisfactorily established. If by mistake the tube has been pushed into the esophagus it should then be immediately withdrawn by the silken loop attached to it, and another attempt made to introduce it into the larynx. The feeding, after the introduction of the tube, should be of liquid consistency, and the patient fed in the most comfortable position possible, which is the one that he will most naturally assume. The reason for this is that no matter what position the patient be placed in, the act of swallowing remains the same, and if placed in an abnormal one, namely in the frequently insisted upon reclining posture, the food, instead of being faciliated in its passage from the mouth into the stomach, is delayed.

The reason liquids are the best is two-fold: First, they are more readily swallowed, and if perchance should accidentally gain entrance through an imperfectly closed glottis, will be more likely to be expelled than a solid particle. The second reason is a physiological one. To quote Foster:[1] "When the substance swallowed is liquid, the movement of the back part of the tongue may be sufficient, not merely to introduce the food into the grasp of the constriction of the pharynx, but to propel it rapidly—to shoot it in fact—along the lax esophagus before the muscles of that organ have time to contract."

In regard to the medicinal treatment accompanying tubage—stimulants, both alcoholic and

[2] Waxham, *Medical Record*, 1887.
[3] This method will materially aid in locating the epiglottis, especially where the patient is young or the edema great.

[1] "Text-book of Physiology" (Revised Edition), Foster, 1895, page 376.

drugs, such as strychnin and digitalis, should be given in sufficient doses from the beginning. If this be done fewer cases of cardiac insufficiency will occur. Mercuric chlorid is the indispensable drug and should be used in every case. Frequent spraying with a two per cent. solution of papayotin, or a $\frac{1}{3000}$ solution of mercuric chlorid, is indicated. This measure not only cleanses the fauces but also relieves the dryness greatly complained of by the patient.

Tincture of ferri-chlorid, although its action upon the blood is not definitely known, is to be given in sufficiently large doses.

The time at which the tube is to be withdrawn depends upon the age of patient, and the severity of the attack. If the patient is young it is better to allow the tube to remain in five or six days. It should then be removed, and if necessity requires, reintroduced. If the patient is older, and the temperature tends to reach the normal, and the symptoms of the disease are rapidly disappearing, the tube may be taken out as early as the second or third day.

In the extraction of the tube the original instruments devised for the purpose should be used. The silken thread should always be removed after the introduction, since it may interfere with the perfect closure of the glottis; or if the case be a virulent one, and ulceration caused by the irritation at the angle of the mouth occur, it will most likely be infected by the disease; and lastly, it may be pulled out during the patient's struggles.

GOOD RESULTS FOLLOWING URETHRAL RESECTION.[1]

BY EUGENE FULLER, M.D.,
OF NEW YORK;
PROFESSOR OF GENITO-URINARY AND VENEREAL SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL;
VISITING GENITO-URINARY SURGEON TO THE CITY HOSPITAL.

WITHIN the last year I have encountered two instances in which, owing to the extensive destruction of the urethral canal, I had originally expected to be finally obliged to establish an artificial route, either perineal or hypogastric, in order to insure a satisfactory and permanent outlet for the vesical contents. In both of these cases, however, by resorting to a very radical and extensive excision of the diseased urethral areas, including also the surrounding cicatrices, I have been able to restore the normal urinary function and to apparently leave the urethral canals of permanently good caliber. In one of these cases the excised tissue included the entire bulbous urethra, fully an inch of the penile urethra anterior to the bulb, and the anterior half inch of the membranous urethra. In the other case, an inch and three-quarters of the urethra was removed. In this second case the tissue removed included the bulbous urethra and the anterior portion of the membranous urethra. The first case was operated on about one year ago, and has been under observation ever since. Although the urethra is somewhat tortuous, it admits freely an 18 American, and shows no special tendency to contract. The second case, done about ten months ago, admitted a 17 American easily four months after the operation. Since that time I have not had an opportunity personally to examine the patient, although I have heard from him that he was all right and in no apparent need of surgical attention.

Before proceeding to give a history of these two cases, a brief review of this surgical procedure will be of interest. In 1882 König was apparently the first one to advocate resection of the urethra. He reported a favorable result from resecting a traumatic stricture of the membranous urethra. The free edges of the urethra were dissected up and brought into apposition by sutures. König supposed, and Heusner also, who, it appears, independently of him reported a similar case a few years afterward, that the success of the operation lay in the healing together by primary union of the cut edges of the urethra. Consequently the operation of resection was supposed to be applicable only to such cases of stricture of the membranous urethra as involved a short portion of its length and as would consequently admit of the cut edges being brought together by suture. Acting on this idea, Wölfler, a few years afterward, resected for traumatic stricture of the membranous urethra a greater section of the canal than would allow of adjustment in apposition by suture of the cut edges of the urethra. To fill up the gap, this author grafted in the necessary amount of mucous membrane taken from a guinea-pig and sutured this foreign membrane to the cut edges of the urethra. He reported a good result. Keyes, inspired by Wölfler's example, grafted a piece of mucous membrane taken from the foreskin of the individual into the space in the membranous urethra occupied by the strictured area. He did not, however, suture this bit of graft to the posterior urethral end. A good result followed this operation. Since then Sapiejko reports that in numerous similar cases he has obtained good results by filling in the space occupied by the stricture with the mucous membrane taken from guinea-pigs, fowls, dogs, and monkeys. In the light of

[1] Read at the meeting of the American Association of Genito-Urinary Surgeons, June, 1896.

subsequent events, however, it seems to me that the good results reported from these cases of urethral resection combined with grafts of various kinds of mucous membrane should be attributed entirely to the resection of the urethra and not at all, as these authors contend, to the grafts. Indeed, one is at liberty to doubt the taking of the grafts in any of these cases, since the only proof of any real weight presented in substantiation of such an hypothesis lies in the fact that the final results in these operations were satisfactory. The same, however, can now be said of simple resection without any attempt at grafting and without bringing the cut urethral edges into apposition by suture. Among other arguments to be advanced against the probable taking of these grafts are the absence of the general conditions favorable to the success of such a procedure, and also the inability to satisfactorily inspect the part involved after the operation. The chief conditions unfavorable to success are as follows: The resected membranous urethra lies in the bottom of a deep, V-shaped space. From the nature of the tissues constituting the angle of this space, it is impossible to so adjust them to those of the under surface of the graft that they should lie in undisturbed apposition. As a result of bleeding or serous oozing and of the contraction of the elastic walls of the V-shaped space, the graft is puckered up and pushed out from the apex of the angle, leaving a triangular space filled with serum or clot between the tissues, which should have been kept in close connection. It may be claimed that a catheter tied in prevents this separation, and possibly it may, although to me it seems very improbable that such should be the case. An ocular inspection of a graft through an endoscope is only feasible after thorough healing has taken place, and at such time the appearance presented by natural cicatrization over a respected area would probably offer no special signs by which it could be distinguished from the appearance which might be due to the taking of a graft. In 1892 Horteloup, Guyon, Albarran, Jouon, Vignard, Wartel, and other French surgeons all announced themselves in favor of resecting areas of the membranous urethra too extensive to admit of the approximation of the cut edges and of leaving the space between these edges to granulate. Horteloup, in his report, announced a case of cure in which, four years before, he had removed four centimeters of the membranous urethra. At that time most of these authors held that resection was applicable only to traumatic strictures of the deep urethra. Guyon and Albarran, however, held that contractile and rebellious strictures of gonorrheal origin could be treated in this manner. In one of the cases reported by Wartel a penile stricture, three centimeters in length, was excised. This is the first report that I find of excision of a penile stricture. Within the last year or so, however, numerous cases have been reported in which considerable portions of the penile urethra have been resected with good results. As a striking example among these cases of resection of the penile urethra in which an especially good result was obtained, may be mentioned the case recently reported by Chismore, of San Francisco. The usual procedure advocated by these French authors after excising the stricture and the surrounding inodular tissue is to introduce a "*Sonde à demeure*," and then to unite the perineal or penile tissues by several tiers of sutures. If the perineal structures heal by first intention, a better result is naturally expected than where suppuration is encountered.

As an after-treatment, I have adopted in my cases a method which has the advantages of the *Sonde à demeure*, without its disadvantages. The advantages of the *Sonde à demeure* in resection involving an extensive area of the deep urethra are that it acts as a splint, as it were, in steadying the cut urethral ends and in affording a firm cylindrical body about which the perineal tissues may be brought and molded so that in healing they may be made to conform as nearly as may be to the shape of the new urethra. The disadvantages of this instrument are that it cannot be removed if its presence in the bladder causes tenesmus. If vesical tenesmus be violently excited, then urinary infiltration into and suppuration of the perineal tissues may result. If the *Sonde à demeure* is once removed to rest the bladder, it cannot be replaced, and in such an event the only thing to do in case firm union of tissues has not taken place is to open anew the perineal wound.

The method I use is as follows: After the resection has been accomplished I make a very low cut, dividing the deepest portion of the membranous urethra, the lowest portion of the perineal structures, and some of the circular fibers of the sphincter ani. Along this low level route I place a soft rubber vesical drainage-tube of large caliber. I then introduce along the urethra a soft catheter of such a caliber that it can be retained with comfort. This catheter extends from the meatus along the penile, the resected, and the deep urethra, down to the big perineal tube, and about it the perineal structures are carefully sutured. This

urethral tube is kept in for a week or ten days, as the case may be. The big perineal tube can be withdrawn and replaced, if needs be, without in the least disturbing the urethral tube.

CASE I.—Forty-five years old. In early life had had numerous attacks of gonorrhea. Ten years ago first began to suffer from obstruction to urination, due to stricture. Shortly after that he was seized with an attack of retention of urine, and was relieved by instruments. Some time after this, his stricture recontracting, he again had retention, complicated with perineal extravasation. This was followed by abscesses and perineal fistulæ. Numerous inadequate attempts had since been made to relieve his condition by instrumentation and cutting and draining the perineal abscesses. When I first saw him, his perineum and his whole scrotum was one mass of induration, riddled with fistulæ. The tumefaction caused by the induration prevented him from sitting upright. No urine passed or had passed for a considerable interval along the penile urethra, but leaked its way constantly out through the numerous fistulæ. After improving his general condition as much as possible, I etherized him. With whalebone filiform bougies the chief fistulous tracts were located. One of these instruments was made to pass along a fistulous tract into the bladder. With the bougies for landmarks, the patient was placed in the lithotomy position and a long, straight, median incision made, extending from the penile urethra in front of the scrotum down to and partially including the sphincter ani. The cut split the scrotum, a testicle lying on either side of it. The whole length of the diseased urethra was exposed. The entire bulbous urethra, an inch of the penile urethra anterior to the bulb, and the anterior half inch of the membranous urethra were found to be in a state of thorough disorganization. Fistulous tracts extended entirely around that portion of the urethra, showing that the burrowing pus had dissected the canal free from its adjacent tissues, leaving that space to be filled in with dense cicatrix. Besides burrowing about the urethra, purulent extravasations had invaded the tissues about the groin and the rectum. From the median incision, radiating incisions were made, laying open all these adjacent pockets. The diseased urethra existed as a hard fibrous cord, perforated in numerous places, and so disorganized and contracted that, on being split open by a longitudinal incision, little remained to mark the course of the urethral canal. This disorganized urethra was accordingly cut out, and the cicatricial nodules from the perineum and scrotum were also removed. In fact, so much tissue was removed from the perineum that in one place little for covering was left save the skin and subcutaneous tissues. A perineal vesical tube and a urethral tube were then put in place in the manner I have already described, and the perineum and scrotum were carefully sutured about the urethral tube. The latter tube was kept in place for ten days and the perineal tube for nearly three weeks. The perineal wound healed by first intention, except in the one spot where little save the skin and the subcutaneous tissues had been left. In this spot a fistulous opening remained for a time, but at the end of six weeks it closed solidly and permanently. At about the same time also the perineal tract along which the vesical tube passed closed. Now the patient is perfectly comfortable, one year after the operation, takes an 18 American sound and urinates normally. To the feel, the perineum and scrotum are soft and natural.

CASE II.—A vigorous man, thirty-six years old, had had trouble from a deep urethral stricture for about a year. This stricture had apparently originated from a preceding gonorrhea. Periodically he had been a heavy drinker. During one of his sprees he was seized with retention of urine. His bladder became overdistended and extravasation took place. I first saw the patient at the Post-Graduate Hospital, where he had been brought about four days after the extravasation had first occurred. During all this time he had not been relieved. His condition was at that time shocking. His temperature was 105°. He was cyanozed. His pulse was irregular and hardly countable. The evidences of extravasation were extreme. His scrotum was about the size of his head. The tissues of the thighs and lower abdomen were much swollen, and hard and porky to the feel. The perineum was very much infiltrated. There was no urine dribbling at the time from the penis. Owing to his condition, hardly more than a smell of ether was considered necessary or advisable. I then made one deep, long cut in the median line along the scrotum and perineum, guarding myself as well as possible from the inevitable outflow of extravasated fluid, which shot out several feet the instant it was liberated. I then made a number of superficial cuts in the scrotum to aid in the drainage. The perineal wound was next examined. On retracting the cutaneous tissues, the whole perineum presented the appearance of a vast slough, rendering it impossible to detect any landmarks. I considered it unwise to try to enter the bladder through the perineum, and it was to that decision that my patient owed his life. At that time I did not, of course, know of the existence of an extensive extravasation between the layers of the deep pelvic fascia, which a cut into the bladder through the perineum would not have relieved. I simply thought that if I entered the bladder through the perineum I should have to do so by plunging the knife through in the median line, thereby tapping the neck of the bladder. If I had tried in a careful way to find the urethra and to enter it back of the stricture, my patient would have been dead long before the completion of the operation, even had it been possible at the time to have found the urethra. I was also fear-

ful of doing damage by plunging the knife unguided through the perineal region. Another very forcible reason which presented itself to me against the perineal opening was that, owing to the extreme slough, I suspected that there had also been great destruction of the urethra, and I felt that, if the patient survived, the case would be one in which retrograde catheterization would eventually be most useful in attempting to restore the urethra and in that judgment I was also correct. I accordingly turned my attention from the perineum to the hypogastrium. I made a longitudinal suprapubic incision, opened the bladder, and gave vent to a great accumulation of clear urine. After the bladder had about two-thirds emptied itself, there came a sudden gush of foul, purulent material, which I discovered to be from an extravasation between the layers of the deep pelvic fascia. After most of this foul extravasation had flowed out, I was able to introduce my finger along the channel from which it came. It burst into the lower portion of the space of Retzius from the right side. A catheter was introduced into the cavity occupied by this extravasation and the place was flushed out with sterilized water. The patient was then put to bed. He rallied quickly, and at the end of two weeks, his condition being good and all the sloughs having come away, I successfully undertook the secondary operation of restoring the urethra. In the two weeks elapsing between the first and second operations apparently no urine had found its way through the perineal wound, and the most careful search now failed to disclose the remains of the urethra in the perineal wound. A catheter introduced at the meatus was arrested by a stricture at the upper margin of the perineal wound, but after a little manipulation it passed into the perineal space, showing a complete destruction of the urethra. That portion of the canal had evidently come away with the slough. A suitable instrument was then passed through the suprapubic cut and retrograde catheterization employed. The position of the posterior stump of the urethra was in this way located. The end of the catheter was cut down upon through a firm mass of cicatrix. The urethra ends were next dissected free from all cicatrices. A tube was passed along the urethra, uniting these cut ends, and a low level perineal vesical drainage-tube also introduced. The perineal wound was brought together loosely and left to granulate about the urethral tube. A small, soft rubber tube was introduced through the perineal tissues in order to drain the perineal space. The tubes were finally removed as in the first case. The suprapubic and perineal wounds all promptly healed, and the urine then came wholly by the urethra. The last time I saw him, four months afterward, he was passing a good stream; was in good health, and a 17 American steel sound passed easily into his bladder. Since that time, as already stated, I have heard that his condition was perfectly satisfactory to himself.

Besides the result obtained in this case from the urethral resection, there are points in connection with its management which deserve special emphasis, and which very likely are original. In this latter connection I refer especially to the employment of suprapubic cystotomy in a case of extensive extravasation of urine from vesical over-distension, not only to drain the bladder, but also as a means of reaching and relieving a deep pelvic extravasation, should such exist. I also doubt if a suprapubic cystotomy has been previously performed, one of the purposes for which was to allow at a future time, of the accomplishment of a retrograde catheterization in connection with a plastic operation on the urethra.

SOME OBSERVATIONS REGARDING MALARIA AS IT OCCURS IN LOUISIANA. ALSO QUININ AS A REMEDIAL AGENT IN THE DISEASE.

By C. D. SIMMONS, M.D.,
of Dutch Town, La.

There has been a great deal of discussion among the physicians of Louisiana relative to quinin as a remedy in the treatment of what is usually termed "Malarial Fever." In the writing of this paper it is not my intention to combat any of the arguments that have been put forth from time to time, to explain the unknown in this field, but simply to record a few facts, gathered along my pathway, that have proven to be rich in malarial findings.

It will be well at this point to mention some of the fevers simulating malaria, and in fact often connected with it, viz: Spring catarrhal fever, typhoid, thermo-malarial, thermic, and puerperal fever.

1. Spring catarrhal fever is of frequent occurrence in my practice, and though it seems to be largely a disease of childhood, it is not always confined to the young, but is met with from the cradle to the grave. Here in this locality I am satisfied that malaria plays an important part in this trouble.

2. Typhoid fever, as met with in the lowlands, is nearly always modified by malarial poisoning. The word "typho-malaria" is delusive, and would lead us to believe that we have a mixed or hybrid fever to contend with. Malaria, like the poor, is with us always, and until we fasten this fact upon our minds and take it with us in our daily rounds, little good can come from any line of study. As a rule, with few exceptions malaria complicates all diseases in the swamp lands of Louisiana, and it does this by being present in the blood for

months or years, before some other disease breaks the powers of resistance that have held it in abeyance.

3. I am confident that there is a fever prevalent here that we may conveniently call thermomalaria. It develops very rapidly during the first hot days of spring, and is very amenable to quinin.

4. Thermic fever has been studied by Drs. John Guiteras and George M. Sternberg, during their stay in the South. I have met with a great many instances of this trouble in my practice. This fever is no doubt due to the extreme heat of our climate, which has a constant tendency to throw out of balance the heat regulating centers. Cold to the head, with the bromids and phenacetin, is our best treatment. Quinin adds to the discomfort of the patient.

5. Puerperal fever has been often mistaken for malaria, but as our knowledge in this field is clearer now, mistakes will not be so frequent. The uterine douche will take the place of quinin in a greater number of instances than heretofore.

6. Malaria, pure and simple, is of frequent occurrence, the tertian type being in the majority, and, as a rule, the disease will stop at this stage if properly treated. When a case of malaria proves fatal, it is nearly always from neglect. The people generally become accustomed to the chill and fever of acute malaria, considering them matters of but little importance, and losing valuable time by taking "Patent Chill-cure," or at most, one or two small doses of quinin. The practice of every physician in this highly malarious district could testify to these neglected cases. Many lives are lost in this way. This will at once account for the large number of these cases that drift into the septenary form of the malady. It is in these neglected cases that we find such immense splenic enlargement. Last year, in a boy of eleven summers, I found a spleen that measured six inches wide by nine inches long, and upon manipulation it seemed to be nearly as thick as it was wide.

How does quinin act to prevent a return of the paroxysms of malaria? Experimental chemists tell us that if we mix tincture of guaiacum with ozonized turpentine, and then add blood to the mixture, the result is a beautiful blue color. This reaction is due to the oxidation of the guaiacum by the active oxygen or ozone found in the blood. If we previously add one part of quinin to twenty thousand of blood, the blue reaction just described is delayed, or does not occur at all. From this experiment we find that quinin has a powerful affinity for active oxygen. So when the drug enters the circulation it is of necessity attracted to the red blood-corpuscles, setting up a protective atmosphere around those life-giving bodies, defying the entrance of plasmodium to the cell.

Let us turn away from the peculiar action of quinin just cited, to a brief study of the parasite that causes the disease. A certain amount of heat, moisture, and oxygen, are necessary to the life of the parasite. For several years I have noticed that the drinking of water from certain wells caused many cases of malaria to develop, but after the first frost no new cases would occur. Now there is but one solution to this and that is, the surface, or near it, is the true producing malarial nidus, hence the surface water, after a frost, does not carry the poison of malaria to the well-water below. From these deductions it would seem that the life of the plasmodium malaria is dependent upon oxygen, as it is found near the surface.

When the plasmodium enters the blood, it, too, like quinin, is attracted to the red cells. This peculiar action is no doubt due to the fact that the corpuscles are oxygen carriers, and thereby supply the parasite with this wonderful element. Both quinin and the parasite destroy the red cells by absorbing their contained oxygen. If quinin is given in full and frequently repeated doses, especially in young subjects, it greatly lowers the normal amount of oxygen. I have noted this effect of the drug in my own practice. By this action sighing respiration is produced, showing a want of oxygen at the base of the brain.

In conclusion, if my theory is correct, the antimalarial action of quinin is dependent on the condition of the red cells; if they are filled up with parasites, their oxygen absorbed, thinned in ranks, disabled for active duty, as we find them in chronic malarial poisoning, very little good can be expected from the use of quinin. In looking about for a remedy to fill all indications, as existing in a condition as pictured above, nothing approaches so near an ideal drug as arsenic in the form of Fowler's solution. It is my belief that arsenic benefits these sufferers of malarial toxemia, chiefly through its direct blood-building power. I have not met with a single contraindication to the use of arsenic in these troubles, which is more than I can say of any other remedy for the disease. I often give Fowler's solution four or five times a day in three-drop doses. In this way it has a tendency to check waste, relieve engorged liver and spleen, and exhilarate the patient. Of course, as a rule, quinin is the greatest of all remedies for malaria, but in just such cases as I have described it will often fail. It is well known to physicians residing

in the malarial belt that quinin often proves a powerful irritant to both the alimentary and urinary tracts. It would be a bold man that would force quinin upon a case like this, by giving it subcutaneously. We have other drugs, such, for instance, as iodin, iodid of ammonia, mercury, nux vomica, iron, the mineral acids, and phenacetin, that serve as well in time of need.

CLINICAL MEMORANDA.

REPORT OF A CASE ILLUSTRATING THE DANGERS OF FORCIBLE AND RAPID DILATATION IN THE TREATMENT OF URETHRAL STRICTURE.

BY JAMES BECKETT, M.D.,
OF CHICAGO.

IN July 1894, I was called to see J. M., aged forty-three, who had been recently operated upon for urethral stricture.

The history obtained was that a few months previous to the operation, he noticed that the stream of urine was narrowed and divided, the desire to micturate becoming more and more frequent, accompanied at times with severe pain, and the quantity diminished.

In this condition he sought the advice of his physician, who arranged for an operation at the patient's home. At the time appointed, he was placed under anesthesia, and sounds ranging from a filiform bougie to a No. 18 English steel, were introduced in rapid succession.

I found the patient five days after the operation suffering from extreme vesical tenesmus, attended with the passage of only a few drops of urine; the abdomen above the pubes was brawny in appearance, boggy to the touch, and exceedingly sensitive ; there was no tumor in the perineum.

On exploring the urethra, a very tight, exquisitively sensitive stricture was discovered 5½ inches from the meatus, so tight indeed that a catheter of the very smallest size could not be introduced.

Hot application (hop poultices) were applied over and above the pubes, and in the perineum, and morphia given hypodermically for the relief of pain and tenesmus; the latter, however, still continued, though in a less aggravated form. A few days later, during a violent straining effort, the patient felt "something give way," which was followed by considerable relief and the escape from the urethra of some ill-smelling matter mixed with a small quantity of urine.

The relief was only temporary, however, the tenesmus returning the following day. From this time the patient began to give evidence of severe constitutional disturbance, rigors were frequent, and delirium marked in the evening and during the night. He continued in this state for several days, passing only a few drops of urine at a time and continually straining, when one morning a fluctuating tumor was discovered which had developed during the night. It was situated about one and a half inches below the umbilicus in the median line. This was immediately opened by a free incision, and a quart or more of urine gushed from the opening, followed by large quantities of foul-smelling pus and several sloughs.

The tenesmus was entirely relieved, the urine passing freely through the abdominal incision. But the patient was left in such a weak and debilitated condition that it was deemed best to wait sometime before proceeding farther, in order to enable him to obtain some sleep and rest, and to get him in the best possible condition for further operation; meanwhile attempts were frequently made to reach the bladder through the urethral canal, but all efforts in that direction proved futile.

It was then decided to open up the canal by perineal section. With the assistance of Drs. W. W. Barkwell and J. F. Burkholder of this city, the patient was anesthetized and placed in the lithotomy position, a Syme's staff passed down to the stricture and forced through it, an incision made into the groove of the staff commencing well in front of the stricture and extending backward about three and a half inches, laying open the urethra, including the strictured portion. The latter was composed of firm, hard cicatrical tissue about a half inch in length and was carefully dissected out. The portion of the urethra behind the stricture was very much disorganized, and after frequent attempts to reach the bladder through the wound, by enlarging the latter and cutting carefully backward in the groove of the staff, a metallic catheter was finally passed and secured. This was left in for forty-eight hours, after which the urine was allowed to drain through the perineal wound.

Recovery was fairly satisfactory; a scrotal abscess developed, and, after being freely opened and drained, healed kindly. Three sinuses were discovered communicating with the abdominal wound, which were also laid open and gave no further trouble. During the past eighteen months I have seen this case frequently. Only a few weeks ago I passed a steel sound (No. 10 English) with perfect freedom into the bladder; no instrument having been introduced for three months previously. The perineal and abdominal wounds had both entirely healed, the stream of urine was free and straight, and the patient strong and active.

It may easily be conceived how a condition as described above may be produced. A patient is anesthetized, and steel sounds of graduated sizes passed into the urethra, and forced through a hard, close stricture, the handle of the sound being depressed between the thighs each time with the intention of including the whole of the canal from meatus to bladder. The point of the sound, however, does not glide smoothly into the bladder as in the normal condition, or as easy as in a case of stricture of large caliber, but is grasped firmly by the strictured portion (according to the size of the sound), which, acting as the fulcrum, produces a very powerful leverage on depressing the handle of the sound. The point of the latter impinges forcibly each time against the anterior wall of the urethra, resulting in either perforation or such a degree of inflammation as to favor suppuration, and eventually rupture and extravasation of urine into the cellular tissue.

In the case cited, the most remarkable feature was the tendency of the urine to burrow upward toward the thorax, at no time was there any tenderness or swelling in the perineum, nor could any sense of fluctuation be felt through the rectum.

I am convinced that this method of dilating rapidly and forcibly within a short period of time, and under anesthesia, is quite frequently practised, and I have been impelled to report this particular case not in a spirit of censure, but to offer it as a plea for the more careful use of urethral sounds and for more exact discrimination between those cases suitable for dilatation, and those which require either internal or external division.

It is a difficult matter to formulate rules of differentiation in the treatment of all organic strictures, but I think the following conclusions may be quoted as being rational and conservative:

1. The surgeon should carefully study the peculiarities of each individual stricture.

2. Rapid dilatation should not be practised with sounds (forcible catheterization), but with a suitable dilator.

3. Gradual dilatation should always be attempted, occupying a period of several days at least before proceeding to internal or external urethrotomy, or to rapid dilatation.

4. When a stricture is extremely sensitive and immediately recontracts after partial or full dilation, dilatation is not only useless, but absolutely harmful and should not be persisted in, with these precautions it becomes an easy matter to decide on the best mode of procedure, with the ultimate cure of the stricture in view.

The operator is enabled to grasp the situation intelligently, instead of going blindly to work with the chances very much in favor of producing some vital injury to the urethra, on discovering which, he becomes disgusted at his own recklessness, and either abandons his patient altogether or discharges him as "cured."

CHOREA AND RHEUMATISM.

BY FREDERICK KRAUSS, M.D.,
OF PHILADELPHIA;
DISPENSARY SURGEON TO ST. MARY'S HOSPITAL; CLINICAL ASSISTANT TO POLYCLINIC HOSPITAL.

THE relation between rheumatism and chorea is still a much disputed question. Many careful observers have concluded that there is a decided connection between these symptomatically diverse diseases. Others are convinced of the contrary.

Sir Dyce Duckworth[1] believes that chorea is simply another variety of rheumatism, in which the brain is affected, instead of the joints. He considers that the definition of Andrew Clark—"rheumatism of the brain"—is very appropriate.

The choreic affection, he believes, is more common in girls, because the primary establishment of menstruation produces certain disturbances in the cerebral circulation that makes the brain a weak spot, which the rheumatic poisons, in certain persons, attack, producing the phenomena called chorea.

This theory becomes more tenable when we consider that both rheumatism and chorea are due to some systemic poison, the nature of which is not exactly known. In the one case, it acts upon the serous membranes of the joints, pleura, etc., while in the other the voluntary motor centers are apparently affected. The ventricles of the brain are serous cavities, lined by serous membranes (endothelium). The internal capsule, through which the voluntary motor fibers run, is in close proximity, especially at the knee, to the lateral ventricles, separated therefrom by the thin layers of nerve-cells, of the thalamus opticus, and the nucleus caudatus, from which fibers run to join it (the internal capsule).

Osler states that in 554 cases, which he had analyzed, 15.5 per cent. had a rheumatic family history, and in 15.8 per cent. of the cases there was a history of articular swelling. The statistics of the Committee of Collective Investigation of the British Medical Association, in a study of 439 cases, show that joint affections were present in 26 per cent. of the cases of chorea, Steiner, on the other hand, in a collection of 252 cases, found only 1.5 per cent. in which rheumatism was present, Osler further asks, "Do these articular affections of chorea belong to true rheumatism? Are they not analogous to the joint troubles of scarlet fever, puerperal fever, and gonorrhea, which no one now regards as truly rheumatic."

In view of this diversity of opinion, it may not be considered superfluous to report the following case of acute articular rheumatism and chorea, the latter occurring after a relapse of the rheumatism. This case is also of interest on account of the extensive heart lesions, which were present as a further complication.

The chorea, occurring during the endocarditis, might be explained also by the embolic theory, though no other symptoms of embolism were present. Another feature is that both the rheumatism and chorea were at first only manifested upon the right side.

J. H., girl, aged sixteen years, was attacked on March 9, 1894, with acute pain and swelling in right ankle and right wrist, and over the precordia. When seen by me next day, she was suffering from a severe attack of acute articular rheumatism, accompanied by the characteristic acid sweats. In addition, there were present mitral and aortic double murmurs and a pericarditic friction sound; marked dyspnea. On palpation over the precordia, the friction fremitus was plainly marked. Temperature 102°; pulse full and short—110 per minute. The patient was immediately placed between blankets and kept absolutely quiet. Blisters the size of a silver dollar were applied over the precordia, giving much relief from the pain. Sodium salicylate was given internally in ten-grain doses, repeated every two hours; milk diet. The patient immediately improved, the temperature on the fourth day being normal. No marked effusion could be outlined in the pericardium, though the friction murmur and fremitus had disappeared. The endocardial murmurs continued undiminished.

Fifth Day.—General condition very good. Was placed upon infusion of digitalis, potass. bicarb. and iodids.

Sixth Day.—Was taken with severe vomiting following ingestion of ham, which the patient managed to get

[1] *Wien. medicinische Blätter*, xvii, 1894.

through an obliging relative. The stomach became retentive after the administration of bismuth subnitrate and carbolic acid. For the past four days there had been a slight epistaxis. This now increased to an alarming degree, but was soon controlled by the snuffing up the nose of a weak solution of Monsel's salt.

The patient did well until three weeks after original attack, when a slight relapse occurred. Temperature 101°; pulse 96. This soon subsided under sodium salicylate, as before.

One week later the patient was attacked with very severe right-sided unilateral chorea, in a few days becoming bilateral. Temperature was again increased, and the cardiac condition became more marked. She was put upon rapidly increasing doses of Fowler's solution.

Five weeks after the original attack another relapse of acute rheumatism occurred, in spite of all precautions in regard to hygiene, diet, and proper regulation of the bowels, etc. This attack quickly passed off, leaving the patient free from the disease to the present day.

Seventh Week.—Chorea has almost entirely disappeared. Systolic and presystolic murmurs at the apex and aortic systolic (obstruction) murmur are heard. Temperature 99°; pulse 100. No albumin in urine. Is taking forty drops of Fowler's solution per day. Slight epistaxis.

Eighth Week.—Chorea has disappeared. Reduced Fowler's solution to fifty drops per day. Patient feels well; appetite good. Temperature is normal; murmurs continued.

Several weeks after this, the patient developed a dry, hacking cough, worse in the morning. Chest examination showed bronchial breathing and dulness over the left apex. These symptoms disappeared under increasing doses of creosote and cod-liver oil.

The heart attained full compensation after a few months, the patient gaining greatly in weight. During this interval the girl's disposition was much changed, being peevish and irritable.

The epistaxis was probably a vicarious menstruation, as she had her first menses four weeks before the beginning of the epistaxis, which latter again returned four weeks later, when it was reduced in quantity, on account of the great anemia.

A CASE OF UREMIA, OPIUM POISONING, AND THERMIC FEVER.

By THOMAS ASH CLAYTOR, M.D.,
OF WASHINGTON, D. C.

THE following is the history of a case admitted to the Pennsylvania Hospital during my term of service as a resident physician on the medical wards of that institution, which has seemed to me to be of sufficient interest to justify its report.

On July 20, 1893, Henry L., aged forty-five, an Englishman, formerly a sailor, was brought to the receiving ward by the police, who had found him lying in an open box-car, exposed to the full force of the midday sun. In his pocket was an empty ounce phial, labeled "Laudanum." At first glance, it seemed evident that he was suffering from poisoning by that drug, for his pupils were contracted to a pin point, respirations sighing and twelve to the minute, face deeply cyanosed, pulse full, but compressible, 122 to the minute, coma profound. His temperature was found to be 105⅘° F. A mild attack of thermic fever was then thought probable, but on closer examination a strongly urinous odor was detected on the breath, also marked edema of feet and legs. The urine obtained by catheterization showed a specific gravity of 1020, acid reaction, a trace of albumin, with an abundance of pale, dark granular and oily tube-casts. The diagnosis then made, and afterward concurred in by my chief, Dr. Morris J. Lewis, was uremia, opium poisoning, and thermic fever. As to the first two, I do not think there is any question or doubt, but as to the thermic fever, we have no positive data, except the high temperature and exposure to intense humid heat, in a close place (the day was very hot and damp).

For obvious reasons apomorphia was not suitable, nor was mustard water or any other mechanical emetic available, because of the deep coma. An attempt to introduce the stomach-tube was followed by slight emesis, but embarrassed the respirations to such an alarming degree that it was necessarily abandoned. The condition was critical, something had to be done, and that without delay, if the life of the patient was to be saved. As the cold bath answered two of the most marked indications, namely, antipyresis and respiratory stimulation, it was at once instituted. The man was placed in a cold bath, with an ice cap to his head, and the hose played upon him. At this time he was comatose, there was constant twitching of the fingers, but no general convulsions.

Examination of heart, lungs, liver, and spleen, proved negative. The reflexes were slightly exaggerated. In twenty-eight minutes his temperature was 104⅕° F., pulse 118, respiration 20, and he showed signs of returning consciousness. Eight minutes later he was removed from the bath. Though his temperature had been reduced and his respirations had risen to normal, the condition was very serious, cyanosis was even more marked, pulse weak and running. He was now given hypodermics of aromatic ammonia, in addition to brandy, strychnia, and digitalis, which he had received during the bath, friction was continued; atropia was used sparingly because of the uremic condition. At 4.13 P.M. (25 minutes later), respirations were becoming deeper and more regular, 21 to the minute, color improving, pulse 136, temperature 102⅗°. At 6 P.M. general condition was improving, temperature 102⅕°, pulse 134, respiration 22. He was now removed to the ward and freely stimulated with digitalis and whisky. At 10 P.M. temperature rose to 105°; there were at this time marked general convulsive movements, which prevented the accurate count of pulse and respirations, but the latter were again shallow and sighing. Patient was again plunged, reducing temperature to 103⅘°.

At seven the following morning he aroused sufficiently to give his name, but immediately relapsed into profound stupor. Urinous odor was very noticeable. Urine was found to contain nine per cent. of albumin by bulk, and casts granular and oily. During the day he received

jaborandi, elaterium, and croton oil, without any apparent result. At 9.30 P.M. the temperature, which had been as low as 102⅘°, shot up to 105⅘°, for which the cold bath was again tried, without effect as to reduction of temperature, but with marked revival from the coma. He then vomited, and shortly after 12 o'clock midnight, had a free evacuation, and was quiet the rest of the night, with a gradual fall of temperature to 100⅗°. The next morning (second day from onset) there was a marked improvement, the patient was perfectly conscious, and gave this account of himself: That he had for some time past been suffering from headache, with dizziness and dimness of vision, had been admitted to one of the large hospitals of the city, but was discharged as having nothing the matter with him; became melancholic, had delusions of persecution, and took an ounce of laudanum with suicidal intent.

On July 22d, (fourth day from onset) though bright and cheerful, was not rational. The temperature fluctuated until the 27th, (ninth day from onset) after which it remained normal. Did not regain mental balance permanently until August 2d (fifteenth day from onset). Though his recovery was slow, and hindered by a mild attack of bronchitis, he gradually improved, and at the time of his discharge, September 15th, was apparently well, except for a trace of albumin and a few casts, which continued to be present in the urine.

The above history naturally suggests the following questions: Was the high temperature, in part at least, thermic fever, or was it due wholly to the uremic poison? Was the uremic attack brought on, or in part hastened by the large dose of opium?

The first brings us to the consideration of the temperature in uremia, upon which opinions seem to differ. According to Labadie-Lagrave[1] reduction of the temperature below the normal in uremia was noted by Kien (1865), Roberts (1868), Hertz, Bilroth, Hutchinson (1870); but Bournville (in 1872 and 1873) was the first who gave himself to a minute study of the symptoms of uremia, and he came to the conclusion that, except in puerperal eclampsia, where the temperature reached 104° to 105.8°, the body heat was lowered. In 1875 Béhier, Lionville, Lacombe, and Hanot, confirmed this view. However, it has been proven more recently that if it is true that in chronic uremia, there is reduction of temperature on the contrary in acute cases, one observes often an elevation, more or less great. Numerous cases have been reported where the temperature reaches 104° F. Jaccoud states that in the common forms of uremia the temperature sometimes remains normal, but more frequently it rises to 102.2° F. or higher. Such was the case in transitory attacks, which ended in recovery; on the contrary, in fatal uremia, the temperature was nearly always lowered, the underwent an ascension high and rapid, or fell to 95° F. Bartels claimed a usual rise in temperature in acute uremia. In case of convulsions it may reach 106° or 108° F. This is seen especially as a terminal rise in cases which have an unfortunate issue. On the other hand, there may be a great reduction, even to 93° or 91° F. This occurs most frequently in cases which end in deep coma, without marked symptoms of motor irritation. Delafield ("American Text-book") claims a rise of temperature above normal. Osler[1] says the temperature is sometimes elevated, but more often it is depressed, and may sink rapidly after the attack. Hughes and Carter[2] state that the temperature is not a fixed symptom. It may be normal or above or below. High temperature more common in parenchymatous cases. In an analysis of forty cases of uremia, pure and simple, the temperature was found to be rather more often below than above normal, the highest being 104.3° and 103.8° F., few above 100° or 101° F.

I am told by Dr. Joseph M. Spellissy, who had the care of nearly one hundred cases of thermic fever at the Pennsylvania Hospital during the summer of 1892, "that a secondary rise within three or four hours after a primary temperature of 109° or more, which has been reduced to 100°, is usual. A second application of cold reduces this hyperpyrexia to moderate fever, lasting a few days. A secondary rise coming on after twenty-four hours from onset, and primary treatment, is the signal of a beginning complication or sequel."

From the above it may be seen that the high temperature, both primary and secondary, may be attributed to uremia alone, at the same time, in view of the fact, that the highest point was reached before there had been any convulsive seizure, and the recovery of the patient, together with the prolonged exposure to intense moist heat, it seems possible that the hyperpyrexia was in part, at least, due to thermic fever.

The second question (was the uremic attack brought on or at least hastened by the large dose of opium?) brings us to inquire into the effect of morphia in disease of the kidneys. According to W. Eliasson, quoted by H. C. Wood,[3] it seems to be established that morphia, at least in part, is eliminated by the kidneys; when given in large doses, morphia appears freely in the urine, but that in small doses it cannot be found, although a substance is present, giving some of the reactions of morphia, from which it is derived. Wood thinks that since in serious kidney disease, the chief channel through which they escape is choked up, opiates should be used with extreme caution. He also states that in one or two cases at the Philadelphia Hospital the administration of morphia was followed by death. Dickinson says that it is not seldom that the comatose state has come on before its time, because of the administration of opium. Labadie-Lagrave name opium among drugs to be avoided in nephritis. On the other hand Dr. A. Loomis, in 1873, advised the administration of morphia in sufficient dose to control the convulsions, claiming that at the same time it produced profuse diaphoresis, facilitated the action of cathartics and diuretics, especially digitalis. Delafield[4] says it is safe to give opium if the arteries are contracted, but if dilated, a very little may cause poisoning and death (arteries are contracted in acute uremia and dilated in chronic. Osler advises morphia. Strümpell only in cases of diarrhea and

vomiting. Hughes and Carter[1] think that full doses may be used with advantage. Its effects must, however, be carefully watched, as they have seen unquestionably bad results from it, especially where uremia complicates fevers.

The majority of clinicians of the present day advise the use of morphia in uremia, at the same time, from a physiological standpoint, it is contraindicated, and while I do not question its advantageous use in moderation, an overdose is, I think, capable of doing harm, by hastening the coma, as was the case with my patient.

MEDICAL PROGRESS.

Twelve Cases of Orchotomy (Castration) for Prostatic Enlargement.—Dr. Maunsell Moullin, before the February meeting of the Harveian Society of London, reported twelve cases of orchotomy attended with generally favorable results. In two cases, both under his own care, death had taken place five and nine days respectively after operation; one death was due to cerebral hemorrhage, the other from fatty degeneration of heart. In two cases, both of which ultimately recovered, traumatic delirium in severe form came on very soon after the operation. In all twelve cases, even inclusive of that which was fatal on the fifth day, there was reported a distinct improvement as to obstruction, and in those cases which remained under observation a sufficiently long time to enable the surgeon to measure the size of the prostates, there was found an appreciable diminution in size, as measured both by urethral and rectal examinations. One case, less successful than others, was that of a patient, eighty years of age, the diminution in size when measured by the finger in the rectum was not very great, and voluntary control was not regained. But as a soft catheter passed easily, whereas before only a metal one or a bougie could be used, and that with difficulty, and as the strangury, which had resisted all previous treatment, entirely disappeared, Mr. Mansell Moullin thought the case could not be considered a failure. It was never suggested that removing an obstruction at the neck of the bladder would be able to regenerate the muscular coat, if this had been destroyed by catheterism and previous cystitis. In another case the inflammation of the bladder persisted, but this again was not the fault of the operation, for the walls contained numerous sacculi, which could not be kept empty.

Respecting the traumatic delirium in two cases, already referred to, Mr. Moullin avers that it is not due to the orchotomy, but to that tendency to delirium that obtains in elderly people after severe injuries, and may even follow the administration of an anesthetic.

Pericarditis Cured by Open Incision.—RULLIER (*Arch. de med. et de pharm. Militairis*, 1896, Nos. 1 and 2). A soldier suffered from serous pericarditis. Four times the pericardial cavity was tapped and the fluid withdrawn. After the fourth aspiration a solution of iodin was injected. The fluid reappeared as before. Rullier determined to treat it as a hydrocele would be treated under similar circumstances. Under cocain anesthesia, an incision was made in the fourth intercostal space, and the pericardium opened and drained. The following day the serous secretion was profuse, but it rapidly diminished and the pericardial wound had closed by the fourth day. Recovery was delayed by a left-sided bronchro-pneumonia but was eventually complete.

At a meeting of the section in medicine of the Royal Academy (Ireland), Dr. O'Carroll (*Lancet*, May 23, 1896) read an account of a cases of suppurative pericarditis secondary to pneumonia, which had been treated by free and constant drainage. The pericardial cavity contained less and less pus, but the patient died from asthenia two months afterward. The walls of the pericardial cavity were found to be adherent everywhere but in front, where there was about a dram of pus. The puncture was made in the fourth space, a thumb's breadth internal to the line of the nipple.

THERAPEUTIC NOTES.

The Therapeutic Employment of Ovarian Tissue.—To prevent the symptoms that often follow surgical removal of the ovaries, and also those so common at the menopause, CHROBAK (*Centralblatt für Gynäkologie*, 1896, No. 20, p. 521) was led to administer ovarian tissue and to practise ovarian grafting. He accordingly had prepared an extract of the ovaries of sexually active and healthy cows, and had undertaken experiments to determine the practicability of ovarian grafting. The extract was employed in six cases in which the ovaries had been removed, and in one in which, with perfectly normal genitalia, the climacteric molimina were severe. In three of the cases of the first group, in which the treatment had covered a period sufficiently long, as well as in the remaining case, distinct improvement followed. The results of the transplantation experiments are detailed by KNAUER (*Centralblatt für Gynäkologie*, 1896, No. 20, p. 524). It was found that not only did ovaries grafted between folds of the peritoneum, or between fascia and muscle, retain for a time, at least, their integrity, but that they also continue to exercise their functional activity, as indicated by the maturation ovisacs.

The Treatment of Cerebrospinal Meningitis with Hot Baths.—Influenced by the successful results reported from the employment of hot baths in the treatment of cerebrospinal meningitis, WOLISCH (*Therapeutische Monatshefte*, 1896, No. 5, p. 254) was led to employ this measure in seven cases of epidemic type in children between five and ten years of age. Perfect recovery ensued in five and two terminated fatally. Of the latter, one was fulminating in character, and in the other the treatment was only imperfectly and inadequately applied. While the number of cases is too small to base a final opinion upon, the impression gained from observation of the cases was that the treatment had a favorably modifying influence upon the course of the disease. The patient is carefully placed in water at a temperature between 90.5° and 92.8° F., and hot water is gradually added until the temperature reaches 104° F., an ice-bag or Leiter's coil being applied to the head.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,

No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, JULY 25, 1896.

THE CHARITIES COMMISSIONERS AND THE "DRINK CURE" AGAIN.

OUR protestations against the outrage which the Charities Commissioners of this city have committed upon Bellevue Hospital and the medical profession, particularly to the physicians who comprise the Medical Board of that Hospital, by allowing the owner of a secret treatment of alcoholism to experiment with it in the wards of a public institution, have been ably seconded, we are glad to say, by the public press of this city, and particularly by the *Herald*, the *Tribune*, the *Advertiser*, and the *Times*.

The fact that the experiment which was suggested by the mayor and ordered by the Commissioners was the outcome of a carefully prepared plan by shrewd men of business, owners of the stock company whose fortunes they endeavored to bolster, has been put forward in a plain and incontrovertible way. If the Commissioners of Charities of New York City persist in the face of the revelations which have been brought to light by the MEDICAL NEWS and the public press, in furthering the interest of this stock company, they lay themselves open to the charge of collusion with a private corporation, and to that of prostituting the privileges of their office to further personal designs.

The gentlemen who are responsible for the present therapeutic fiasco at Bellevue Hospital, whether the onus of it lies with the chief executive of this city, as the Commissioners would have us believe, or whether it rests with the Commissioners themselves have been seized with such a desire to counteract the drink habit that it amounts to an obsession. Such fanatical enthusiasm is not begotten among strictly business men by unalloyed motives of humanity, and to conceal the actual motives behind such attempted explanation is puerile, wilfully evasive, and ludicrously absurd.

Why, it may reasonably be asked, should the Commissioners of Charities lend themselves to the test of a substance which has nothing to commend it save the biased representations of its owners, and the commendation of an ubiquitous newspaper man who has the ear and the confidence of his honor, the Mayor, when they can satiate their *furor experimentiæ* with a substance like the Keely cure, which, until a year or two ago, was supported and advocated on grounds of personal experience by hundreds of individuals whose talents and positions entitled them to be heard with faith and respect? To be sure the Keely cure is now, practically, a thing of the past, and exists only in those recesses of our memory where things which we would forget are stowed. But before its dissolution it fulfilled the inventor's purpose; it gave him notoriety, which a few mistake for genuine fame, and it made him wealthy.

Must we go through the agonies attending the birth of another Keely cure only to find that the travail brings forth a dead issue, merely to satisfy the rudimentary aspirations of the present Charities Commissioners' board? We implore the Commissioners to spare us the chagrin and pain of bearing further witness to their rude and impotent endeavors. If they hearken not to our counsel we shall be put to the disagreeable task of pointing out to them, in detail, how they have neither the right

which they claim, nor the privilege, to which they aspire, to pursue their present course. The necessity of construing for them the simple rules which should govern their conduct so that they may be relieved of the horrible imputation of being a board of puerile *dilettanti*, we trust may also be spared us.

THE ASSOCIATION OF AMERICAN MEDICAL COLLEGES.

THE study of pedagogy is coming to occupy a prominent position in the curriculum of our colleges and universities. In this direction the University of Pennsylvania, the University of Chicago, and Columbia College have made the most philosophic advances. In a popular way the association of teachers, which has just completed its session at Buffalo, shows a vigor and enterprise which promises much. We have before us a very strong article on medical pedagogy prepared during the past spring by a committee on the Association of American Colleges and though this work is incomplete, we shall look with unusual interest for the full report which may be expected in the course of another year. This is, we believe, the first effort to consider medical education from the modern pedagogic standpoint. This syllabus, as it is called was prepared at two conferences held in Chicago and Detroit during the months of February and March of the present year, and it attempts to give an outline of an ideal course of study for a medical school and some definite details as to the equipment of each department, the cost of this equipment and the method of presenting each group of medical studies.

The committee first fixed upon a unit, which was termed the recitation period. This period was assumed to consume, for classroom work and study, two and a half hours of the student's time. The minimum year in a medical school was assumed to consist of six hundred of these recitation hours, or twenty recitation periods a week for thirty weeks, and a proportionate number for schools having longer or shorter terms than thirty weeks. The committee recommends the division of the term into two semesters of three hundred recitation periods each.

Some very definite information is given on page 6, of the syllabus to teachers preparing students for admission to medical schools.

The disposition of the course of study during the four years of six hundred recitation periods each, is given in four graphic diagrams which appeal at once to the eye. These diagrams show that the committee consider general chemistry a study which ought to be required on admission. The large amount of space given to anatomy, physiology, pathology, and the small amount of space given materia medica will not receive the immediate approval of all of our readers, nor will the relegation of the clinics to the third or fourth years exclusively, be considered wise or rational. The simple course of study of the old medical schools has hardly prepared us for the rather complex course of study recommended in this syllabus. We are at a loss also to understand why anthropometry should be introduced into the medical curriculum, and why two or three recitation periods should be given to elective students during the last three years. In regard to electives, the committee urges that all colleges allow a small margin of electives to begin in the second year, and that each college make this work cover such branches as it is able to offer in the best quality. The value of even a small proportion, say five-one hundredths, of elective work, cannot be overestimated when the resources of the school are such as to permit. Properly conducted, the electives allow a choice of work adapted to the needs or inclinations of the students.

The syllabus then discusses in detail the method of teaching anatomy, histology, physiology, and pathology, and gives a very minute account of the equipment and management of these departments. This is probably the most valuable portion of the syllabus, and if it could receive the careful consideration of our medical faculties, it would not only improve the character and quality of the laboratory work, but it would economize and systemize this very important department of our medical colleges. The portion of this syllabus for which Dr. W. S. Hall and Dr. D. H. Galloway are responsibe, is most deserving of commendation. We expect to see equally radical recommendations in the next report of this com-

mittee upon the direction, equipment, and pedagogic spirit of the more practical branches of the medical curriculum.

THE DIAGNOSTIC VALUE OF THE APPEARANCE OF THE TONGUE.

ALTHOUGH there have been some clinicians who have had the temerity to assert that the appearance of the tongue gives us no information of value as to the state of the digestive apparatus or the general system, physicians almost without exception, examine this organ with considerable care in all important cases. While it may be true that when making a diagnosis, too much importance should not be attached to this organ, it is also a fact that he who ignores it, deliberately puts aside a diagnostic aid of no little significance.

The three conditions which we should note in examining this organ are its coating, its movement, and its shape. The coating, which upon the posterior part of the organ is smooth, pasty, and yellow, nearly always indicates a condition of hepatic torpor or biliousness, or if it be white and rather dry and rough, this coating may, in an adult, point to the excessive use of milk. Again, every one with experience knows that the tongue is one of the most efficient aids to diagnosis that we have in the earliest stages of enteric fever, when it appears rather more narrow than normal, with a coated center and bright red edges. Later on its slow projection and retraction on the demand of the physician indicates clearly the degree of mental hebetude and the physical depression of the patient. The coating of the tongue in enteric fever, which is very heavy and discolored if the mouth is not well cleansed by the nurse, shows the perversion of salivary secretion and epithelial growth; and the lips and teeth, covered by sordes, indicate that the patient breathes through his mouth and fails to move his tongue. Again, in childhood we find three conditions of the tongue of considerable diagnostic import. One of these is the broad and flabby tongue seen in the state, called by Eustace Smith, "mucous disease," in which all the mucous membranes of the body are affected by a catarrhal process. Scattered through the grayish coating of such a tongue, which is usually smooth and very moist, are patches in which the epithelium and the coating have been shed, leaving red spots which have an irregular outline, somewhat resembling that seen in the markings on a worm-eaten leaf.

The second of these conditions of which we have spoken, is that of the tongue in acute gastric catarrh. The coating, which is both light in weight and color, has scattered over it bright red dots which are not raised above the surface and are very numerous. Somewhat like this tongue is the so-called "strawberry tongue" of scarlet fever, in which the red fungiform papillæ project above the coating.

In advanced exhausting disease, such as diabetes or tuberculosis of the lungs, or abdominal viscera, the tongue often becomes narrow, hard and pointed, forming what is called a "parrot tongue," a state of this organ which speaks ill for the patient's recovery. In all grave fevers, a moist tongue is a hopeful sign, and a dry tongue an evil omen.

Unilateral coating of the tongue may be due to a decayed or ragged tooth, or to a disordered function of the second division of the fifth nerve.

Discoloration of the tongue may be due to bismuth or iron when the color will be black; to laudanum, chocolate, or tobacco, when it will be brown, and, therefore, any marked change in its appearance indicates the drug or food which the patient has swallowed.

The color of the tongue itself is also worthy of note, for it is extremely pale in the anemia of renal disease, of chlorosis and pernicious anemia, and cyanotic and blue in the advanced stages of those diseases which interfere with the proper oxidation of the blood.

Scars on the tongue, or the presence of freshly made bites of its edges, discovered by the patient on arising from bed, may indicate the unrecognized presence of a nocturnal epilepsy; an ulceration, if it be single, may be due to a chancre or epithelioma, in which case the cervical glands may be enlarged. Again, multiple ulcerations, if chronic, may be due to tuberculosis or to the mucous patches of syphilis. If the ulceration is

acute, it is probably an attack of ulcerative stomatitis.

The movements of the tongue are also worthy of note. If paralyzed from an attack of hemiplegia, we will find that it is protruded toward the paralyzed side, and it may become immobile in glosso-labio-pharyngeal paralysis. Tremors of the tongue not only are seen in the late stages of exhausting diseases, but in numerous nervous affections, such as bulbar paralysis and in insular sclerosis. It is also often affected by tremors in paretic dementia and chronic alcoholism. Finally spasm of the tongue may occur, generally as a manifestation of hysteria.

H. A. HARE, M.D.

ECHOES AND NEWS.

Smallpox at Gloucester. — Since the beginning of the present epidemic, 1995 cases of smallpox have occurred at Gloucester, England. A few cases are still reported each week, as well as an occasional death.

A Resignation.—Dr. Mazyck P. Ravenel has resigned the position of bacteriologist to the State of New Jersey. He will shortly leave Princeton and return to Philadelphia, where he will act as director of the laboratory for the Pennsylvania Live Stock Commission.

Mr. Lawson Tait and the British Medical Journal.—From indications that seem to abound in England at the present time, Mr. Tait is going to unroll a large bundle of discord at the approaching meeting of the British Medical Association. A strong enemity has existed between him and Mr. Ernest Hart, the editor of the journal, for a number of years.

Venereal Disease in the British Army in India.—According to a recent report made by the Sanitary Commissioner with the Indian Government, the British Army in India suffers more from this class of diseases than any army now in existence. During 1894, an average of over three thousand soldiers were constantly disabled from this cause alone.

The New York Post-Graduate.—The fifteenth annual announcement of the New York Post-Graduate Medical School and Hospital has just been issued. Five hundred and forty-two physicians from all over this continent have recorded their names at the institution during the past year. More than one thousand operations were performed in the Hospital, while nearly twenty thousand patients were treated in the outdoor department.

The Views of Professor Langerhaus.—Since the report of the investigation regarding the unfortunate death of his child after an injection of diphtheria antitoxin, Professor Langerhaus has published a letter in the *Berliner klinische Wochenschrift* in which he asserts his adherence to his original views concerning the death.

Instructors for the Blind.—The American Association of Instructors of the Blind met in Pittsburg on the 14th instant. Many thoughtful and interesting papers were read. It is a matter of surprise to note that one essayist deprecated the idea of teaching music to the blind, because, he believed, the musical talent possessed by them was greatly inferior to that of other people, and hence the time thus occupied was to a degree wasted.

Pathology by Telegraph.—An English exchange takes occasion to point out the inaccuracies of telegraphic reports of scientific news, by which great injustice is often done scientific investigators by presenting their work in a ridiculous light. An instance is given of the New York agency reporting a cure for acute mania, which consisted in the withdrawal of four ounces of cerebrospinal fluid by lumbar puncture. The comments were not less remarkable than the statement.

Beriberi and Drinking Water. — The *British Medical Journal* gives a brief account of two epidemics of this disease occurring on board vessels whose crews were perfectly healthy until they were forced to take water from ports where beriberi was prevalent. About four or five weeks after beginning the use of this water, the disease made its appearance, this period corresponding very closely with the recognized period of incubation for the malady.

The Wilhelm Meyer Memorial.—On the authority of Dr. Felix Semon, it is announced that the sum of 20,000 marks required to erect a memorial to the late Dr. Meyer of Copenhagen, the discoverer of adenoid growths in the pharynx, has already been subscribed and the success of the undertaking is assured. It is with pride we observe that the United States has contributed a larger sum than any other single nation. The amount of relief that has been conferred by the use of Dr. Meyer's suggestion in this country alone is immeasurable.

A New Parisian Affection.—An epidemic of mumps has made its appearance in Paris, chiefly afflicting adults. The reason why this infantile malady should now attack those of mature years, in whom an invasion during childhood seems to give no immunity, is yet a mystery to the physicians.

The Protection of Blood-Brotherhood. — In the light of modern inoculation by the injection of blood from the immune, it has been suggested that it may be possible to protect African explorers by blood from the healthy natives. In the case of Stanley, it is known that he submitted to the transfusion of native blood some fifty times in the practice of the rite of blood-brotherhood, and it is not impossible that to this was due his exemption from the fatal fevers of that climate.

Silver in Surgery.—Although the ophthalmic surgeon has long recognized the efficacy of silver as an antiseptic.

Professor Credé of Dresden, has recently presented the further claims of this metal to the attention of the general surgeon. Lactate of silver is an excellent germicide, but its easy solubility (in fifteen parts of water) renders it rather dangerous as a dressing. The citrate, however, is only soluble in 3800 parts of water, and is therefore quite safe. It is found that a dilution of silver of even 1–80,000 still retains appreciable antiseptic qualities, while a solution of sublimate weaker than 1–20,000 is worthless. A novel suggestion is the use of thin sheets of metallic silver spread upon linen cloth as a protective dressing in surgery. It is claimed that even in the occurrence of suppuration, the action of the products of the bacteria produces a lactate of silver, which prevents their further development.

A Code of Medical Ethics.—To the graduating class in the medical department of the University of Pennsylvania, Dr. H. C. Wood said: "Consider every member of the profession as one of your own family, and having an inherent right to your medical services, but do not abuse this right, consider any discovery or invention you may make as belonging to the general profession; never in any way laud your own medical skill or attempt to supplant in public or private estimation one of your medical brethren; join as soon as may be the incorporated companies of your fellows for scientific and social intercourse, and for the cultivation of that professional conscience which often binds men more closely than their personal sense of right and wrong; through good and ill report, stand by members of your own profession, unless they be guilty of moral evil."—*Medical Age.*

Their Vocation Mistaken.—A heavily veiled woman recently asked for a private interview with the janitor of the Baltimore College of Physicians and Surgeons, in which she solicited the assistance of that institution. She stated that a man who had done her a wrong for which she wanted to be avenged, was now an invalid and in her power; and she wished a physician sent who would quickly dispatch him, after which the College could have him rapidly dissected, thus avoiding the possibility of detection. She had understood that such acts were often performed by medical colleges, and for this favor she would pay handsomely.

The New Medical School for Women in Russia.—Miss Bogolubska, a Russian women, obtained a medical education in countries outside her own. She returned to Russia after graduating from the University of Berne, but was not allowed to practise as a physician. But sick people she would care for, and set to work as a nurse. She had been born in a mining village and understood the common people. She had worked eight years, when, in the cholera of 1892, she was allowed to labor among the cholera-stricken peasants. Her labors afforded such an object-lesson that the Czar allowed her to take the Russian degree, which not only gives her the right to practise in any part of the empire, but a medical school for women, which is thronged with applicants, has been reopened, after having been closed for political reasons, largely through this example.

The Medical News at the Johns Hopkins.—In the *Johns Hopkins Bulletin* for May–June, is a long list of the medico-scientific publications, chiefly journals, that are available in the public and private libraries of Baltimore. Only one journal, the *Archiv of Virchow*, is set down as being in six libraries. The *Lancet* and *British Medical Journal* are to be found in four, while the MEDICAL NEWS is in five. No other American medical periodical, if the *Index Catalogue* be excepted, has a greater number of friends. The last-named publication is in six libraries. Seventeen libraries only are taken into the account. Of these, ten are the property of institutions, while seven of them belong to members of the teaching staff at the Hospital. Among the latter are Drs. Welch, Osler, Kelly, Halsted, and Hurd.

Lemuel Shattuck, the Pioneer Sanitarian of Massachusetts.—The current number of the *Boston Medical and Surgical Journal* has, in its editorial columns, the following reference to one of the file-leaders in American sanitation, Mr. Lemuel Shattuck. It says: "The report of the 'Sanitary Commission of Massachusetts,' which was presented to the Legislature in 1850, has been justly characterized as 'the first *great* step in the sanitary work of our times,' in the United States. The report was chiefly the work of Mr. Lemuel Shattuck of Boston, chairman of the commission. 'I remember Mr. Shattuck well,' said Dr. Henry I. Bowditch, in his 'Centennial Discourse on Public Hygiene,' in 1876, 'calm in his perfect confidence in the future of preventive measures to check disease, he walked almost alone the streets of his native city, not only unsustained by the profession, but considered by most of them as an offense. . . . The public, ignorant of hygiene, treated him no better. The report fell still-born from the State printer's hands. Its recommendations were ignored.' Prominent among the more comprehensive measures urged by Lemuel Shattuck, the following may be mentioned: The establishment of a general board of health for the State; the appointment of a local board of health in every city and town; the adoption of a general and uniform system of registration of births, deaths, and marriages; the taking of a decennial census, beginning with 1855; the revision of the laws relating to coroners; the control and regulation of cemeteries by boards of health. The development of public and municipal hygiene since the Massachusetts State Board of Health and Vital Statistics was established in 1869, has followed to a striking degree the lines marked out by Lemuel Shattuck in 1849."

The Cholera Bacillus in Subjects Apparently Healthy.—The Cairo, Egypt, letter to the *London Lancet*, July 4th, contains reference to several cases of the presence of cholera bacilli in apparently healthy people. The communication is probably from the pen of Dr. Armand Ruffer, who went from England to become the chief bacteriologist to the sanitary office of the Egyptian

Government. The writer makes the following statement: "It was during the Hamburg epidemic that German observers pointed out that a man apparently well and at his usual vocations might yet contain the comma bacilli in his intestines and be a potent means for spreading the disease. Several cases confirmatory to this have been seen in Cairo this month, and there are now two men in one of the cholera hospitals who were sent there on suspicion from different villages, because each of them was seen to vomit once by a native medical man searching for cholera. They both looked extremely well, and complained bitterly at having been brought to the hospital among a lot of dying folk. Both denied all diarrhea and previous vomiting, but the stools showed unmistakable bacilli, and continued in both cases to show them a week after admission to hospital. There are many things yet to be learned about this fell disease."

SOCIETY PROCEEDINGS.

ONE HUNDRED AND FIFTEENTH ANNIVERSARY OF THE MASSACHUSETTS MEDICAL SOCIETY, HELD IN BOSTON, JUNE 9 AND 10, 1896.

(Concluded.)

C. E. EDSON, M.D., of Roxbury, read a paper upon

THE PULMONARY INVALID IN COLORADO.

He said that a short distance on the eastern slope of the mountains, in the "invalid belt," meant a great difference in the climatic conditions. This was particularly true of the neighborhood of Colorado Springs. It was evident, therefore, that it did not suffice to send a person simply "to Colorado Springs." A most important point was to have the patient under constant and proper medical supervision at Colorado, for on arrival there the fight had only just begun. The City of Denver is often smoky, and a city anywhere is not a desirable place for the pulmonary invalid. East and west of the city the atmosphere is quite clear, and the elevation one thousand feet less than that of the Springs, and much more comfortable to many invalids. Montclair, University Park, and Berkley are suitable locations. Outdoor life in Colorado, he said, did not necessitate "roughing it," and should not do that. At first there is almost a magical gain in weight, but the bronzed face and the appearance of health do not indicate the true condition of the chest. After a relapse, often the result of imprudence, the improvement is not nearly so rapid as at first. The secret of success in Colorado is living a large part of the time in the open air, but without exercise or exertion. At first the elevation alone causes sufficient pulmonary work. After a few weeks the patient should begin by walking not more than an eighth or a quarter of a mile, steadfastly resisting the desire to do more. Care should be taken to select a house with a sheltered porch. Horseback riding is to be long deferred, and most cautiously begun, for it had proved a dire cause of hemorrhage. This same objection applies with double force to bicycling. Driving may be indulged in almost from the start, providing a jolting vehicle be not selected. The speaker said that the warmth is all in the sunshine. Thus, he had seen the thermometer in the sun register 90° F., and at the same time, a short distance away in the shade, the thermometer would stand at 40° F. This should be borne in mind by the invalid. Pulmonary invalids should be particularly careful to avoid many of the exciting outdoor sports of the West, as well as the seductive pleasures of the smoking-rooms of the clubs. The West is essentially a *man's* country.

V. Y. BOWDITCH, M.D., of Boston, read a paper on

THE TREATMENT OF PHTHISIS IN SANITARIA NEAR OUR HOMES,

Based upon five years' experience in the sanitarium for pulmonary diseases at Sharon, Mass. He said that, so far as he knew, this was the only institution of the kind in Massachusetts intended only for consumptives of limited means. In a previous paper, read before the Climatological Society, in Washington, D. C., in 1895, he had reported upon forty cases of consumption treated at Sharon. Ten were reported as arrested. Of twenty-four treated in the last two years, seven left the sanitarium with an arrest of the disease. Of the remaining seventeen, one was a suspicious or doubtful case. She left at the end of four months in perfect health. In twelve others, phthisis was more or less advanced in one or both lungs. Eight showed a greater or less improvement, and four did not. Five of the ten cases reported before the Climatological Society as arrested had left the sanitarium subsequently in good condition. It was impossible in a paper to convey to others the impressions made upon the clinician by actual observation of the patients. He would say, however, that the percentage of cases of arrest or cure of tuberculosis in the sanitarium had been larger than he should have expected under other circumstances. He was aware that it might be objected that in some instances the diagnosis had not been confirmed by finding the tubercle bacilli in the sputum, but it was known that the absence of bacilli was no proof of the absence of tubercular disease, and to him a certain change in the character of the percussion note, or of the respiratory murmur in the apex of the lung, associated with fever, malaise, and loss of flesh, meant infinitely more than the mere evidence of the microscope alone, whether positive or negative. Out of sixty-four cases of phthisis treated in the sanitarium in the last five years, twenty-two were classed as arrested. In two, the disease reappeared a few months later. Of the three who died, one died from some abdominal tumor, without evidence of pulmonary disease; one died of some rectal disease, and the other died of pulmonary tuberculosis, after having gone back to a mode of life which had been expressly forbidden by the medical advisers. Granting that, as Austin Flint claimed, about eleven per cent. were self-limited, he felt justified in maintaining that the results given rest on something much more than a mere self-limitation of the disease, and that they warranted the establishment of similar institutions in the vicinity of large cities or towns. He still felt convinced that fresh air, sunlight, good food, judicious exercise were the chief factors in whatever good results had been obtained. The so-called "peppermint cure" had been tried without any

special results, so far as any curative action was concerned, although in some instances it seemed to diminish the cough. Klebs' antiphthisin had been tried carefully in several cases, but with negative result. Creosote had been used, but without any special evidence of benefit, except as regards its action on digestion. He had never been able to give the large doses of creosote recommended by some physicians, owing to the disastrous effect on the stomach. Tuberculin had not been used, because of a former experience, which had led him to advise against it. Regular hours of sleep, rest in the open air, even in the coldest winter weather, regulated exercise, and pulmonary gymnastics were the important elements in the treatment. He had never seen any harm from the pneumatic cabinet, and many patients had spoken of the relief it afforded to the breathing. The usual tonics were freely given, and special attention was paid to the condition of the stomach and bowels. If patients were feverish, quiet was recommended, rather than exercise. The floors and walls of the sanitarium were wiped, not swept. A special endeavor had been made to secure for these persons occupation in the open air after they had recovered sufficiently to leave the sanitarium. He had been surprised to find how quickly these patients became contented and happy in the sanitarium.

DR. F. I. KNIGHT, in discussing the paper, said that as long as the treatment of tuberculosis was the treatment of the condition of the patient, and not of the disease specifically, the closer the medical supervision, the better the result for the patient. After an almost endless search for specifics, we had fallen back upon the treatment of the general condition of the patient. This held good as much in Colorado as at home. As had been said, the effect upon the patient of knowing his condition and of being surrounded by other pulmonary invalids was not deleterious. He called attention to the danger of allowing these patients to make merry beyond their strength, as was too often done. The moral effect of a sanitarium was desirable, as impressing upon the patient the fact that it was a serious fight for life and health. In one of the German sanitaria there was a wise motto hung on the walls: "Patients do not come here to be amused, but to get well."

ALFRED WORCESTER, M.D., of Waltham, presented a paper entitled

THE TREATMENT OF TUBERCULOSIS BY THE INJECTION OF TUBERCULIN AND ITS DERIVATIVES.

He said that while the finding of tubercle bacilli in the sputum was a useful confirmatory test, the absence of such bacilli did not necessarily exclude tuberculosis. Personally, he would prefer to rely upon the clinical evidence of the disease. The tuberculin test was far more reliable, for long before the general health had been affected, or the tubercle bacilli had been thrown out in the sputa, this test would reveal the presence of tuberculosis. Its value in diagnosis could be easily demonstrated; it was different regarding its therapeutic value. Perhaps the best work in this line has been done by Professor Brieger, in the Berlin Charité. In his own work he had endeavored to follow out what he had seen done there by Professor Brieger. The diagnostic value of tuberculin was due to its poisonous effects upon the tuberculous, when given in doses which would not prove poisonous to the non-tuberculous. It was perhaps not well known that by giving small doses of tuberculin daily to a tuberculous patient, an immunity to tuberculosis could be established in such an individual. This constitutes the modern therapeutic use of tuberculin. He believed that this acquired immunity to the poison of tuberculin was often a great advantage to the tuberculous patient. It was claimed by some clinicians that pure tuberculosis caused no fever, but whether this was so or not, it should be remembered that tuberculin is suitable only for non-febrile cases, for it is essential that the tuberculin treatment be carried out in such a manner as to avoid the occurrence of fever.

In his own experience, tuberculin alone had been used in five cases, with antiphthisin in two cases, and antiphthisin alone in twenty-two cases. The general treatment was the same for all. The peppermint treatment had been used in a number of cases, but it was found impossible to use the original mixture on account of the large quantity of alcohol it contained. However, the inhalation of the peppermint had been found so soothing to the cough that it had been continued. In his cases the temperature had been noted every two hours by day, and every four hours by night. He had used pure tuberculin in seven patients. In two there was so much difficulty in establishing a tolerance that antiphthisin was used instead. No harmful results were observed, and only once was there abscess formation. This was due to the failure to observe the cloudiness in the tuberculin, and its unfitness for use. Two of the five cases in which only tuberculin was used had recovered sufficiently to be practically well, and to return to their occupations. Two of these patients appeared to be in a desperate condition, and he should not have expected from their appearance at the commencement of the treatment that they would have lived so long. If he were correct in his observations upon these particular cases, he certainly had been remiss in the past, because he had seen many such cases go on from bad to worse until death had kindly brought relief. It was better, he thought, to try to do all we could for suffering humanity —to be a deluded optimist, than a scientific pessimist. If it were true that each organism excretes its own specific poison, and that the bacilli excrete a particular poison, each of its own kind, then it was possible that tuberculin contained besides the poison affecting the animal preyed upon, the specific poison for the bacilli themselves. If it could be shown that the death of the bacilli were caused, not by exhaustion of the proper food in the culture medium, but by the excretion into it of their particular poison, then we might reasonably hope for the isolation of this poison. What we needed was something which would kill the bacilli of tuberculosis in the tuberculous patient without injuring the patient in any way. Professor Klebs claimed that this had been found in his antiphthisin, which was supposed to be composed of a chemical modification of tuberculin, containing all the germicidal and curative principles, without the toxins. This claim had certainly been bitterly disputed, but it had also been supported by many competent observers. Of the twenty-two cases which he

had treated with antiphthisin, ten had been in such an advanced stage of the disease that if none had improved it would have been little to the discredit of the treatment; but in four there was marked improvement, and of the five which did not improve, in only one was the treatment carried out for more than a week or two. He had certainly been greatly encouraged by his experience with antiphthisin, even in these nine desperate cases. Nine of the cases were not nearly so ill, yet a number had not shown the improvement one would have naturally expected, and three had grown worse. He would say, therefore, that the cases treated with tuberculin had done better than those treated with antiphthisin.

R. H. CHITTENDEN, M.D., of New Haven, presented a paper upon

NUCLEINS AND NUCLEO-PROTEIDS IN THEIR RELATION TO INTERNAL SECRETION.

He said that it was now known that the removal of the pancreas or liver caused death, because of the deprivation of the system of those internal secretions emanating from these glands, and influencing the general metabolism of the body. Experiments had shown that the pancreatic gland poured into the blood some secretion which destroyed the sugar in the blood, and which was absolutely essential to the maintenance of the physiological equilibrium. This was not true of all glands, at least not to the same extent. It had been shown that in the suprarenals the active principle of the secretion was obtained only in the medulla of the gland. The secretion of these glands is soluble in water, dilute alcohol, and in aqueous solutions it dialyzes readily through parchment; hence, the active principle cannot be a proteid body. It was moreover fairly stable, and also fairly resistant to the action of the gastric juice. Its physiological power was destroyed by the action of alkalies, oxidizing agents, and by continued boiling. It was apparently a powerful reducing body, and by oxidation, a rose-red color was produced, accompanied by a rapid loss of physiological action. It had been estimated that one eight-hundredth of a grain of the pure active principle was sufficient to produce physiological results on the heart and arteries of an adult man; hence the amount actually elaborated by the suprarenal gland must be exceedingly small.

The thyroid principle is an organic iodin compound, containing a large proportion of iodin and considerable phosphorus in organic combination. Thyro-iodin can be prepared from the thyroid glands of man and animals by boiling the glands with sulphuric acid, or treating them with digestive fluids. The iodin is in firm combination. The bulk of the compound consists of an albumin and a globulin. The physiological activity of the thyroid gland has been proved by experiment to be due to thyro-iodin, and excessive doses of this substance produce the same symptoms as large doses of the thyroid gland. To the chemist it seemed evident that the different gland cells must be endowed with a distinctive form of cell activity. Cell protoplasm, whatever its origin, has a certain uniformity of composition, and the most characteristic bodies were the nucleo-albumins and the nucleo-proteids. They are characterized by containing more or less phosphorus. Nucleic acid is a white, amorphous powder, soluble in water, and having a strong affinity for all proteids. It contains as much as ten per cent. of phosphorus. But under the head of nucleic acid we had to deal with a large class of bodies, giving a diversity of internal structure, clearly suggestive of corresponding differences of function. One or more of these acids was to be found in every cell of the body, generally combined with some form of proteid. The ready convertibility of these nucleins, and the fact that many other catabolic products may be obtained from them, afford good reasons for believing that the nucleins and the nucleo-proteids are the most probable antecedents of the internal secretions.

E. S. BOLAND, M.D., of South Boston, presented a paper upon

EXTRAUTERINE PREGNANCY IN ITS RELATION TO THE GENERAL PRACTITIONER.

He said that from June, 1891, to June, 1896, he had attended 851 pregnancies, and had met with five cases of ectopic gestation. All five ruptured before the diagnosis was made. They were operated upon, and made a good recovery. He thought it probable that many of these cases were overlooked, or wrongly diagnosticated. The pinched face, clammy perspiration, shallow breathing and feeble voice, and the feeble and irregular pulse, should lead the physician to at once conclude that some terrible abdominal accident had happened. If these symptoms were associated with a history of irregular menstruation or cessation of the flow, there was good ground for believing that one had to deal with a ruptured ectopic gestation. He had not found digital examination per vaginam of much value after rupture, except in excluding uterine pregnancy. The discharge of decidua had occurred in almost all of his cases. In two there had been nothing characteristic of the true condition until the occurrence of rupture. After this occurrence the physician should be able to make the diagnosis, and should insist upon prompt operation. Ice had been recommended by some to check the hemorrhage, but if it were depended upon, it was probable that the undertaker would continue its use. The operation should, whenever possible, be done by a competent surgeon. The after-treatment should embrace the use of sterilized salt solution and strychnia.

M. H. RICHARDSON, M.D., of Boston, gave an abstract of his paper on

ECTOPIC GESTATION,

Referring particularly to the diagnosis and treatment. He said it was admitted generally that conception took place, in the vast majority of cases, in some part of the Fallopian tube. The observations regarding the occurrence of abdominal pregnancy are now believed to be unreliable and misleading, and that supposed cases of abdominal pregnancy are really due to rupture of a tubal gestation. Out of 60,000 cases treated in Braun's clinic in seven years, only five were extrauterine pregnancies. Formad, in 3500 autopsies, found thirty-five cases. Modern observations, however, show that it is by no means so infrequent. In one year at the Massachusetts General Hospital, out of about 300 laparotomies, there were twelve operations for

extrauterine pregnancy. He had seen several cases in which rupture of a tubal pregnancy had taken place before the time of the occurrence of the next menstrual period. The commonest variation in menstruation is that in which the flow is delayed for a few days or weeks, and when it does begin is usually scanty or irregular. It had been found that under the microscope differentiation could not be made always between the decidual shreds and those passed in some cases of dysmenorrhea. The diagnosis of extrauterine pregnancy was not usually difficult. He had known it to be mistaken, however, for a simple miscarriage, and also the diagnosis of extrauterine pregnancy to be made in cases of subserous fibroids. Between rupture of an extrauterine pregnancy and rupture of other sacs the diagnosis was often very difficult. Hemorrhage from chronic salpingitis and from other sources made it impossible to establish the diagnosis in the absence of the usual signs of pregnancy. Under special conditions, the policy of palliation might be employed, but ordinarily prompt laparotomy was the only proper course. Were the objections to laparotomy tenfold greater, he would still recommend this operation as the best and safest method of treating extrauterine pregnancy. In intraperitoneal ruptures immediate abdominal section was demanded in every instance, except where the patient was evidently moribund. With prompt resort to these modern methods of treatment, he thought, in time the mortality from extrauterine pregnancy would be as slight as the mortality is now from normal pregnancy.

H. P. BOWDITCH, M.D., of Boston, delivered the annual discourse upon

VIVISECTION.

He took for his theme the recent effort of the anti-vivisectionists to secure by legislation the prevention of vivisection. He said that it needed no professional education to know that medical science must be based upon physiology. Physiology could only hope to advance by a resort in certain instances to vivisection. The opposition movement sprang from one of the noblest instincts of the human breast—the desire to prevent suffering. In considering this "misguided benevolence" one was reminded of a recent utterance of Mr. Roosevelt: "Conscience without common sense may lead to folly, which is the handmaiden of crime." These people imperatively demand, not the restriction, but the total abolition of vivisection. Some of the leaders even deny the right of the human race to profit by the sufferings of animals. It should be remembered: (1) That those who are in charge of the institutions where vivisection is practised are equally competent to determine the existence of cruelty as those constituting the rank and file of the anti-vivisectionists; (2) that no abuse of vivisection has been shown; (3) that the governing bodies have both the will and the power to put a stop to such abuses should they occur; and (4) that existing statutes furnish sufficient protection against vivisection, as well as against cruelty at large.

In 1874, in England, a Royal Commission was appointed to investigate this subject. The Commission entirely acquitted the English physiologists of the charge of cruelty, and pronounced a merited eulogium upon them. But the action of this Commission was remarkable, for it acquitted the accused, but placed them under police surveillance for life! The law growing out of this work of the Commission was still more remarkable, for it made it penal to torture domestic animals in any way, whereas wild animals might be tortured as much as any one might desire, provided only that it was not done for scientific purposes! The first outbreak of the anti-vivisection movement in this country occurred in New York in 1881, when, under the leadership of Mr. Henry Bergh, an attempt was made to secure a law for the abolishment of vivisection. After the exposure of the garbled evidence upon which this advocacy was based, the legislature refused to pass such a law, and went so far as to furnish distinct protection to the men of science in the legitimate use of vivisection. The President of the Massachusetts Humane Society not long ago called attention to the failure of anti-vivisection movements in various parts of the world, and suggested that the Society should coöperate with the medical profession for the proper restriction of vivisection. Unfortunately the Society has not acted upon this sound advice.

Turning, then, to another aspect of the question, the speaker called attention to the fact that we knew nothing whatever about pain, except that it was a subjective sensation. We were often struck by the different degrees of suffering experienced by different individuals under apparently the same circumstances. There was apparently a rough proportion between the acuteness of pain and the degree of intellectual development. It was entirely impracticable, therefore, to draw reliable conclusions regarding the sensations of the lower animals, based upon a comparison with our own sensations under similar circumstances. All that we know about this is derived from the cries or other external evidence of some condition which the economy repels. Even such highly developed animals as the horse and the dog often furnish evidence that they do not experience pain in the same degree and manner as the human subject. These external evidences of suffering are reflex movements, and it is well known, may take place under partial anesthesia, without the existence of consciousness. The "spasm of agony" of sensational writers is, therefore, better described as a nerve-muscle reaction. Dr. Bowditch suggested a proper definition of pain would be: "Consciousness of the excessive stimulation of a sensory nerve." This definition excludes those cases in which the brain is narcotized, or separated from the rest of the nervous system.

But there still remained, he said, to be considered the question of how far it is the right of one individual to suf fer for another, and how far may future good compensate for present evil. To this he would answer, that we unhesitatingly submit ourselves and those we love to physical suffering, in the hope of future benefit. The law which bids us bear one another's burdens is a beneficent one, and we cannot escape from it if we would. But vivisection involves suffering of a lower animal for the benefit of the whole human race, and for all time. Moreover, physiologists, in their experiments, cause suffering utterly unsignificant when compared to that inflicted upon animals, for little or no cause; so that as far as the charge of cruelty

is concerned, the physiologists may claim exemption on the same ground as the sportsman; and as regards the justification for the infliction of pain, the advantage is in favor of the physiologist. Again, the relations of animals to each other are such as to justify, from a moral point of view, an indictment of cruelty against Nature herself. There is usually less suffering in connection with the animals operated upon or killed in the laboratory than there is in these animals in a state of nature. Aside from a feeling of mercy, the physiologist, for the sake of convenience, uses an anesthetic, in order that the struggling and cries of the animal may not distract his mind from the subject in hand or derange his delicate instruments. It has been calculated by Professor Yeo that seventy-five per cent. of the animals are rendered absolutely unconscious to pain by the giving of an anesthetic, but the mere administration of an anesthetic to an animal is not as an agreeable process as to the human subject. In trifling operations it is much better, probably, for the animal not to give an anesthetic. Of the twenty-five per cent. of operations done without an anesthetic, it is probable that twenty per cent. are about as painful as vaccination, four per cent. as painful as the healing of a wound, and one per cent. as painful as an ordinary surgical operation performed without an anesthetic.

Now, what have we gained from vivisection? The foundation of our science—the discovery of the circulation of the blood—was made possible only by examinations on living animals. The proper mode of applying ligatures to arteries and the antiseptic treatment of wounds have reached their present state of perfection chiefly by experiments on animals. The surgery of the past has been robbed of much horror simply by this introduction of the use of the ligature instead of the use of torturing hot irons. The therapeutic use of antitoxin in diphtheria shows already that the physician has within his grasp the means of successfully treating one of the most dreaded of diseases. Who will dare to say that this boon has been dearly purchased by the lives of a number of guinea-pigs? Commercial experiments illustrating the danger to life of sewage-polluted water have cost many thousand human lives, whereas the knowledge which has enabled us to guard successfully against cholera has cost the lives of a few mice! We should remember the words of Him who said: "Ye are of more value than many sparrows."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 23, 1896, TO JUNE 29, 1896.

Major Daniel M. Appel, Surgeon, is relieved from duty at Fort Porter, New York, and ordered to the new post near Little Rock, Ark., for duty.

Captain Aaron H. Appel, Assistant Surgeon, is relieved from duty as examiner of recruits at Chicago, Ill., and ordered to Fort Porter, New York, for duty.

Leave of absence for one month, to take effect about the 5th proximo, is granted Captain Walter D. McCaw, Assistant Surgeon, Fort Ringgold, Tex.

Leave of absence for two months, to take effect on or about August 1, 1896, is granted Major Louis M. Maus, Surgeon, Fort Sam Houston, Tex.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 30, 1896, TO JULY 6, 1896.

Leave of absence for two months, to take effect on or about July 8, 1896, or as soon thereafter as practicable, is granted Colonel Charles T. Alexander, Assistant Surgeon-General.

Captain William B. Davis, Assistant Surgeon, will, in addition to his present duties, take charge of the Medical Supply Depot in New York City during the absence on leave of Colonel Charles T. Alexander, Assistant Surgeon-General.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 7, 1896, TO JULY 13, 1896.

The extension of leave of absence, on account of sickness, granted Major James C. Worthington, Surgeon, is further extended one month, on account of sickness.

Leave of absence, for two months, to take effect on or about July 15, 1896, is granted Colonel Dallas Bache, Assistant Surgeon-General, Headquarters Department of the Platte.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 4, 1896.

June 29th.—Surgeon I. G. HENEBERGER, detached from the marine rendezvous New York, and ordered to the hospital Widow's Island.

Passed Assistant Surgeon E. S. BOGERT, ordered to the New York Navy Yard, July 2d.

Passed Assistant Surgeon T. C. CRAIG, detached from the New York Navy Yard, July 2d, and ordered to the marine rendezvous, New York.

July 2d.—Passed Assistant Surgeon W. F. ARNOLD, detached from special duty in China and Japan and ordered to return home.

Assistant Surgeon H. F. PARRISH, ordered to the Naval Laboratory, New York City.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 11, 1896.

July 7th.—Medical Inspector J. C. WISE, detached from the Washington Navy Yard and ordered as a member of the Board of Inspection and Survey, July 15th.

Medical Inspector R. A. MARMION, detached from the Board of Inspection and Survey, July 15th, and ordered to the Washington Navy Yard.

Passed Assistant Surgeon S. S. WHITE, detached from the Naval Academy and ordered to the "Thetis."

Passed Assistant Surgeon G. A. LUNG, detached from the "Thetis," ordered home, and granted two months' leave.

July 8th.—Surgeon P. A. LOVERING, detached from the New York Naval Hospital and ordered to the "Oregon."

Passed Assistant Surgeon C. H. T. LOWNDES, detached from the Washington Navy Yard and ordered to the Naval Hospital at Philadelphia.

July 10th.—Surgeon C. U. GRAVATT, to Norfolk with draft of men, and then home and three months' leave.

Assistant Surgeon R. G. BRODRICK, to the "Franklin."

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 18, 1896.

July 14th.—Surgeon R. C. PERSONS, orders to duty at Naval Hospital revoked and ordered to continue on present duty.

Passed Assistant Surgeon H. N. T. HARRIS, ordered to the Pensacola Navy Yard.

July 15th.—Surgeon S. H. DICKSON, ordered to the "Texas."

Assistant Surgeon J. M. MOORE, detached from the Naval Hospital, Norfolk, and ordered to the "Texas."

July 17th.—Assistant Surgeon A. FARENHOLT, detached from the "Monterey" and ordered to the Mare Island Hospital, Cal.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXIX. NEW YORK, SATURDAY, AUGUST 1, 1896. No. 5.

ORIGINAL ARTICLES.

TUBERCULAR PERITONITIS.[1]

BY ROBERT ABBE, M.D.,
OF NEW YORK.

THERE is probably no surgeon of much experience to-day, who has not encountered in his abdominal operations some phase of peritoneal tuberculosis; and, it is fair to say, he has often been confronted with it unexpectedly. The more one studies the subject, however, the more it is cleared of obscurity, and takes its place as an entity to be thought of in all cases of doubtful diagnosis in abdominal enlargements. The sudden invasion of the peritoneal cavity by the tubercle bacillus is announced by signs which have their counterpart in the joints, in the meninges, in the pleura, and in synovial tendon sheaths —and give a diverse series of phenomena.

It has been customary, in writings upon this subject, to adopt a classification dividing tubercular peritonitis according to its gross anatomical appearances, into ascitic, dry, and caseating forms. It gives a somewhat fairer understanding of the subject, however, if we consider the multiform varieties of its exhibition from the standpoint of the bacillus, and observe that each case represents a stage in the life history of the bacillus, and its results. We then see that under the varying conditions we may have: (1) An eruption of miliary tubercles on the peritoneal surface so acute that acute infectious diseases, or even strangulated hernia, have been suspected. Operations have been resorted to, in the hope of relieving obstruction, which had caused vomiting, constipation, distention, and pain. Acute miliary deposit with inflammation and a little serum only were encountered to explain the trouble; or (2) an enormous accumulation of ascitic fluid, with rapid wasting, slight pain, and no fever, has been found to follow a slower deposition of tubercles widely scattered over the peritoneum; or (3) a persistent pain or tenderness of the abdomen, with moderately tympanitic distention and irregular areas of dulness, associated with slight afternoon temperature and loss of appetite or flesh, have been found to indicate diffused tuberculosis of the peritoneal cavity without fluid, but with a varying amount of plastic exudation partially sealing its walls together; or (4) wasting of the body with irregular tympanitic distention, fever, anorexia, and sweats, associated with huge cakes of matted lymph and omentum, or sacculated ascites, or pus, have been found on operation to illustrate the latest steps of tubercle development, with caseating deposits of lymph, purulent degeneration of ascitic fluid and cicatrizing masses of gray miliary deposits; or (5) the mishaps incident to degeneration of caseating patches ulcerating into the bowels, causing fistulæ or extravasations of feces into the peritoneum; or bowel obstruction by lymph adhesions, or bands—these add to the picture of the multiform manifestations of tuberculous peritonitis, once known as *tabes mesenterica*; (6) and finally, a retrograde course in the life of the bacillus and its products may leave an abdominal cavity partly sealed by the atrophied tubercular elements which may give the patient years of comparative health.

The mode of entrance of the bacillus is undoubtedly various in different cases. It is probably less often through circulation in the blood than by direct entrance through perforation of the intestinal wall or transit from the Fallopian tube. Leaving out the cases where miliary tubercles are found on the peritoneum adjacent to the base of a tubercular ulcer of the intestines, or the cases where a perforating appendical ulcer is surrounded by them, or those where the primary deposit is about the tube or ovary, there are still a larger number where no focal deposit suggests the point of entrance, but they are scattered uniformly over the visceral, parietal, and omental peritoneum. These are not uncommon in children, and indeed, are usual in cases with large ascitic collections. It has been thought probable that in such cases milk-food has been the carrier, and it would seem probable that penetration by bacilli of follicles, minutely ulcerated or not, is the most reasonable method of entrance. A case of Bradford's, where the lad had this typical form and was known to have fed on the milk of a tuberculous cow for some weeks prior, is in evidence. It would take but a few cases to establish this view.

As illustrating another method of infection, I would quote a recent case of my own, in a lady who had been losing flesh for half a year, and

[1] Read before the American Surgical Association, at Detroit, Mich., May 26, 1896.

who, though not aware of fever, had been having frequent night sweats. A slowly developing trouble in the appendix region culminated in an acute febrile attack (T. 103½°; P. 130), and local peritonitis, with a mass, which I supposed to be only an ordinary appendical abscess. On operation, the mass was composed of the caput coli, appendix, small intestine, and omentum densely matted, and all studded with miliary tubercles, with a couple of ounces of free ascitic fluid. The appendix had to be dug out forcibly. There was no abscess, but a tubercular ulcer of the mucous membrane of the appendix, which had penetrated all the coats, showed where the bacilli had made entrance.

Vierrordt reports the case of a girl of but 6½ years, with tubercular peritonitis preceded by a purulent vaginal discharge in which tubercle bacilli were repeatedly found, suggesting the vaginal route as possible in children of unclean habits.

Burdon-Sanderson, Sturgis, and Carr, in searching for the starting point of tuberculosis in children, review autopsies of several hundred, and conclude that about one-third die of tuberculosis in some form. Walter Carr shows that in one hundred and twenty autopsies, the enlarged thoracic glands show in two-thirds as the point of entrance, while the mesenterics are involved in one-sixth.

Thus we see that whether the infection gains access by the alimentary or pulmonary route, the bacillus must be early disseminated. That it is possible, however, for it to be a confined and local malady—contrary to Louis' law that "after puberty the lungs are almost always affected when any other organ is involved," is shown by Carr's 120 autopsies, where in 12 it was limited to one organ. In König's report of 2230 *post-mortems* at the Göttingen Pathological Institute, there were 107 of tubercular peritonitis, of which 99 had coexisting phthisis. Eighty had ulceration of the bowels.

That it has been found to be generalized when studied from the autopsy point of view, is not an argument for such cases as come to the surgeon's notice when a recognized local point of entrance may have still confined the disease to that focal area. While studying the curability of the disease, however, we may well keep in mind the fact that though it may be disseminated, the system may yet recover, as after other bacterial infections, and by ridding the abdomen of its nest of infection, the system may be put in an attitude to overcome the rest.

Up to recent years, and even of late, the best clinical observers have held that tubercular peritonitis is incapable of spontaneous cure. It may be fairly said, however, that recovery from chronic peritonitis with ascitis had been heretofore observed, and, with the above dictum in mind, writers have claimed that those could not have been tubercular, else they would not have recovered. This argument in a circle now stands refuted. Bouilard found in extensive search of older literature eighty-two cases of tubercular peritonitis of which twenty recovered. In some cases good health persisted ten to seventeen years after recovery. One man, quoted from Louis, twenty-four years old, had marasmus, pleurisy, and abdominal ascites. Being attacked by Asiatic cholera was nearly purged to death, and then made an excellent recovery.

Vierrordt of Heidelberg, claims much success in curing by medical measures. Among other cases he quotes that of a girl of 6½ years, without lung trouble, who had a purulent vaginitis bearing many tubercle bacilli. She was soon cured of this, but later developed a slight stomach pain, which rapidly increased to great proportions, doubling her up with anguish. She grew pallid, had tympanites with ascites and diarrhea. The dulness increased, with tenderness to pressure and continued intestinal pain. The temperature was sometimes elevated, and as often subnormal. The diagnosis was undoubtedly tubercular peritonitis, but she made a good recovery.

McCall Anderson reports (1894) a boy of nine years, delicate, with persistent cough, and rapid loss of flesh during three weeks. He was admitted to the hospital two weeks after his abdomen had begun to be painful. He had diarrhea, distention with ascites, with dull areas of lymph exudate in the front and sides. A wave of fluid was easily elicited. He had bronchitis (T. 100 to 103°, P. 140), hectic and sweats. His diarrhea was arrested; ice-cloths were applied to the abdomen, giving relief whenever the temperature rose above 100°. He remained in the hospital several months, and made a recovery in every particular.

Comby reports two cases. First, was a child, pale, and with a large, painless belly. The abdomen was like a hemisphere filled with free fluid. Nothing abnormal appeared about the chest, or heart, or urine, to account for the abdominal state. The child had lost a brother with tubercular meningitis, and the parents had phthisis. A purgative, sulphur baths, and milk diet were given. In one week there was amelioration. Calomel purgation was given with improvement, and the child was allowed to go to his parents. One year

and a half later it was brought back in perfect health, with supple abdominal wall and no ascites. In a second case, a woman with vague abdominal pains and a temperature of 101°, showed pulmonary crepitation and dull areas. The abdomen was distended, and showed a caked mass in the peritoneum, with evident peritonitis of a subacute form. Consultations were held, and it seemed proved that she had pleuro-peritoneal tuberculosis. She was given creosote pills and podophyllin purgation, and recovered.

Marfan reports seven cases satisfactorily treated with medicine alone.

Such claims as these, which are scattered here and there through journals, and based on clinical evidence without bacteriological proof, seem to me to be worthy of credence, and I am willing to think there are many mild cases spontaneously cured by medical means. Indeed, it would be presumptuous to claim for surgical measures what we do if the powers of nature are not credited with a large measure of successful effort. The overthrow of the tubercle bacillus in its stronghold in diseased bones, joints, spine, lungs, synovial sheaths, and even the meninges, is to-day so universally recognized that *a priori* we must grant the probability of its conquest in the peritoneum. But the disease has not yet been taken out of the domain of medicine entirely. Since Spencer Wells, in 1862, cured the earliest recognized tubercular peritonitis case, encountered by accident in removing a diseased ovary, and since König advocated, in 1884, the general resort to laparotomy in all cases of tubercular peritonitis after he had cured three cases, there has been a very general resort to this method, and a sustained confidence in its results when applied properly.

The two classes of most value as proof, are those surviving for several years, and those who, having died from other causes, have given opportunity to see that the miliary tubercles present at operation have disappeared or become altered and reduced to innocuousness. In illustration of the latter, a case by Guignabert is of moment. A woman of thirty, with abdominal pains and vomiting, and tumor to the right of the middle of the abdomen, and evident tubercular peritonitis, is reported. On operation yellow serum was evacuated, and tubercles found studding the peritoneum and abdominal walls. The mass constituting the tumor was composed of adherent viscera and mesenteric glands. Antiseptic solution was used to bathe the surface, and she left the hospital cured. Returning in a fortnight for a plegmon of the neck, of which she shortly died, autopsy showed no fluid in the peritoneal cavity. The congested bowels had returned to a normal gray, and it was impossible to find a trace of the many tubercles visible at laporotomy, except at one small spot. The retromesenteric glands were caseating and shrinking. The intestine was not ulcerated. Another case is reported by Osler where Halsted had cured a classic case of tubercular peritonitis existing six months, in a woman of twenty-eight years, by washing and draining. The intestines were matted and tubercular. Councilman had found bacilli. She recovered, and returned to the hospital weeks after with acute pneumonia, of which she died. Autopsy showed some adhesion along the scar, and a few adhesions with the omentum, but none between intestinal coils. Over the peritoneal surface there were some few flat tubercles, mostly near the ileocecal valve. A recent pleurisy and pneumonia were present, but a most critical examination failed to reveal tubercles therein. The peritoneal tubercles were still rich in bacilli, but undergoing fibroid changes. Kümmel quotes several cases where late autopsy showed entire absence of tubercles where they had been seen at operation one or two years previous. In a recently reported case of Dr. Hamill of Philadelphia, a woman of twenty-four had for two years suffered a decline in health so that she was reduced to a condition of exhaustion and emaciation. Examination showed a painful abdomen distended by ascites. The right ovary was enlarged, and tubes and ovaries adherent. Laparotomy in November, 1894, revealed a thickening of peritoneum to four times its normal. A large ascitic collection was evacuated. All the viscera were extensively adherent to each other, and the omentum and all were thickly studded with miliary tubercles. Adhesions were broken up, and thorough irrigation with boiled water was given. She made a rapid convalescence and gained flesh. One year later a ventral hernia called for an operation. The peritoneum was normal in thickness; no ascites had reformed. There were no tubercles on the peritoneum, a very few on the intestines, and more on the ovaries and tubes. These latter were removed. Irrigation and closure without drainage resulted in primary union. The patient made a quick recovery, and was apparently restored to perfect health.

Of the hundreds of cases operated on for every stage of the disease, the recoveries have been estimated at twenty-five to eighty per cent., and of these, the great majority have survived from six months to several years.

After reading the reports of every case of which mention is made in the French, German, and English, I find the points worthy of attention to be, the variety of stages at which the disease has been attacked; the methods of operation; and the theories of curative action. The cases most favorable reported are undoubtedly those where an acute or a subacute inflammation with ascites has been operated on simply by abdominal section, with evacuation and immediate closure. Most operators have added to this the detergent effect of boiled water irrigation or the alterative action of natural salt solution, or the mild antiseptic action of boracic acid, weak carbolic acid, thymol, mild bichlorid of mercury solution, or camphor naphtol, or iodoform, powdered or in emulsion. In no case does there seem to have been any disposition to absorb the antiseptic. In fact, the altered condition of the peritoneum must render it less liable to absorb. Most successful cases have been drained, either by a tube or iodoform wick, or a Mikulicz tamponade, yet evacuation alone is apparently capable of curing, even though immediate suture of the abdomen is done. In the dry form, that is, with notable presence of miliary tubercles, with or without plastic exudate, but no appreciable amount of serum, there would seem to be a call for some specifically acting material to affect the free bacilli, and here most often the use of chemicals has been made. The liberal use of iodoform in glycerin emulsion seems more than justified in the cases reported in the German clinic. The most striking treatment with pure camphor naphtol has been advocated by Guignabert in his thesis, 1894. It is the method of Rendu. After reporting several cases where the camphor naphtol was injected through a cannula to the extent of half an ounce after the ascites had been evacuated, he quotes the case of a woman of thirty, with grave symptoms, and a dry, tubercular peritonitis. A sponge wet with camphor naphtol was brushed over the entire exposed intestine wherever involved, and the abdomen closed. She recovered promptly. After six months she returned with a phlegmon of the neck, of which she died. Autopsy showed an entire disappearance of miliary tubercles and a restoration of inflamed intestines to a healthy gray.

In another case of a boy of fourteen years, with many liters of ascites and miliary tubercles everywhere in the peritoneum. After laparotomy he sponged the affected bowel with camphor naphtol, and had the pleasure of witnessing a perfect recovery, with dry peritoneum months afterward.

In a boy of twelve years whose abdomen contained flocculent fluid, circumscribed and confined by matted intestines and abdominal walls everywhere studded with tubercles, the cavity was washed with camphor naphtol and closed. A complete cure was maintained long afterward. In another patient of twenty-five, whose abdomen was as distended as a seven months' pregnancy, seven quarts of clear fluid were evacuated and ten grams of camphor naphtol injected through the cannula. In a month a noticeable caking had taken place in the abdomen, which softened in another month with retraction of the abdomen. It seemed to follow a course like the absorption of a pleurisy. The patient steadily gained in weight and made a perfect recovery, with no hardness, dulness, or tenderness.

In a girl of sixteen years, with night sweats and ascites, he evacuated six quarts of clear fluid and injected 5 c.cm. of camphor naphthol. No reaction or fever followed. Slight pain and thickening of the omentum occurred. Convalescence was perfect, so that one month later there was no pain, thickening, or ascites. A ginuea-pig inoculated with ten centimeters of this ascitic fluid had rapid tuberculosis, and at autopsy on the twenty-ninth day had tuberculosis of the peritoneum and liver.

Berger reports two cases thus treated with benefit and without accident, though both had phthisis, and succumbed within five months. In advocating camphor naphtol, Guignabert describes it as having the effect of iodoform, without poisonous properties. It is an unctuous, white liquid, made by fusing one part naphtol and two parts camphor—which fuse with heat—and may be filtered and kept stoppered. Being insoluble in water, it is distributed under its own form by peristalsis, and is claimed by M. Perrier to have remarkable antiseptic action, especially antagonistic to tubercular bacillus, as is shown in tubercles of the mouth, pharynx, larynx, bones, joints, and glands. It is slow to be eliminated, slow to be absorbed, and produces no local necrosis of tissue. It seems to be especially worthy of trial in cases where the dry tubercle is exposed on the surface of matted and separated bowel.

Direct medication of the miliary tubercles by camphor naphtol, or by iodoform, dry or in emulsion, represents the greatest proportion of attempts to cure, pointed at the life of the bacillus. Yet the greatest number of cures have been without direct medication. The surgical world has not yet recovered from the surprise that followed Wells' and König's advocacy of simple laparotomy, and we therefore find a considerable pro-

portion of remarkable cases cured after evacuation only by simple incision. Nevertheless, the fact that evacuation alone of the ascitic fluid by trocar has been a lamentable failure, has resulted in the advocacy of irrigation by Thiersch solution, or sterilized water, weak carbolic, or bichlorid solution, or by normal saline solution. Each of these resorts has the same excellent cures to show. Even the ballooning up of the peritoneal cavity by sterilized air after the evacuation of ascites has been advocated by Von Mosetig, and several excellent cures reported. This is well illustrated in a paper by Folet of Lille, one of whose patients was in perfect health eight months later. She was a woman of forty, with a cured pleuro-bronchitis, followed by tubercular peritonitis with grave ascites. The fluid was drained by trocar, and air insufflated into the abdomen until she was greatly distended. The result was entirely benign. The appetite returned, fever left, the air was absorbed, no fluid re-collected, and, except for a remnant of pleuritic trouble, she was cured.

The value of medication, then, must be discounted. Much speculation has filled the literature on the subject as to why cure results. The first theory naturally considered the traumatism in opening the peritoneum as responsible. Then the contact of air with the serous membrane was credited with an unexplained curative action. The formation of adhesions as a protection to the absorbing surface; the specific action of radiated sunlight, which Koch has shown would kill tubercle bacilli; the access of bacterium of putrefaction normal to the air, and which are antagonistic to the tubercle bacillus; the simple diminution of pressure of ascitic fluid favoring recuperative heart and lung action; the vague term psychical influence; the reflex effect of peritoneal operative handling; all have been advocated in many languages, but have failed to give satisfaction.

The theory that is sustained by most facts is that based on the life history of the bacillus; the capacity of the animal economy, not only to suppress the activity of the organism by encapsulating it, but to remove it by absorption. The proper opportunity for conquest is not afforded in the presence of ascitic fluid, which aids as a veritable culture bouillon, and by its fluidity aids dissemination. When, however, the peritoneum has been aroused by congestion, which follows evacuation, and an inflammatory action is set up, engendering cell hyperplasia wherever the irritation of bacilli is felt, the intruder is walled in. Retrograde degeneration soon sets in, and the morbid material is absorbed slowly but surely until as many cases now record, the peritoneum may become normal where a few weeks or months before it was studded with miliary bodies. The same retrograde change seen frequently after laparotomy where disseminated sarcoma or papillomata have been discovered, makes an analogous clinical picture.

König and others accept the idea that fibrous transformation of tubercle is induced by the leucocytosis or hyperplasia following the substitutive and healing inflammation after laparotomy, or, as Roersch put it, the laparotomy does not cure, but only aids nature to bring it about. Some recent experiments by Manniotti and Baciochi on rabbits and dogs, to determine the influence of laparotomy on induced tubercular peritonitis, are interesting. In dogs, a cure always resulted; in rabbits not so, though improvement was common. The tubercles were absorbed and transformed into connective tissue, though some were slow to disappear. Irrigation with sterile water or antiseptic solution have no value in bringing about a cure in experimental cases. Their conclusions are that the inflammatory reaction established, with an increase of absorptive power, is curative. Very recent experiments by Gatti and Vassilevsky, show also retrograde changes by degeneration of epitheloid cells rather than by phagocytosis.

In conclusion, then, we can say, that now, more than at any time in the past, it is the imperative duty of the surgeon to freely evacuate by incision all fluid of a tuberculous peritonitis. In all probability, additional perfection will be obtained by irrigation with normal salt solution, and closure of the abdomen. Where advanced tubercular deposits can be sponged over with camphor naphtol, it is probable some additional good will accrue. The cure in undoubted tubercular cases may be absolute, though remnants of disease are apt to be latent. The purulent form of tubercular peritonitis is amenable to the same treatment. As regards the general disseminated tuberculosis, with tubercular peritonitis, we must, if we read the cases aright, regard that as occasionally capable of cure. Patients in almost moribund condition with extensive ascitic form, have been frequently restored to health. The treatment by puncture may be dismissed as inadequate. The power of the peritoneum to suppress a widespread tuberculous infection cannot be doubted, and its mode of action is through reparative inflammation, embedding the bacilli,

and forcing retrograde metamorphosis. Cure has frequently followed a second laparotomy when the ascites has reaccumulated—which is the exception.

THE RELATIVE IMPORTANCE OF THE STOMACH AND THE OTHER DIGESTIVE ORGANS.

BY A. L. BENEDICT, A.M., M.D.,
OF BUFFALO, N. Y.
LECTURER ON DISEASES OF THE DIGESTIVE ORGANS, DENTAL DEPARTMENT, UNIVERSITY OF BUFFALO.

THE popular estimate of digestion makes it a function of the stomach alone, the mouth, pharynx and esophagus constituting a comminutor and hopper device for supplying the stomach, while the intestine is thought of merely as a sewer. Within comparatively recent times, the medical opinion on this subject has swung to the opposite extreme of regarding the stomach as a reservoir for food, in which maceration and some preliminary digestion are provided for. The development of gastric chemistry on a clinical basis, has caused the pendulum of medical opinion to swing back again almost to the extreme of the old professional and present popular view. The former extreme was due to the existence of speculative philosophy without research on physical and chemical lines, the modern extreme to a pragmatic devotion to technic without sufficient theorizing or assimilation of observed facts. The man who must wash out every stomach and apply the same routine of chemical tests, without due consideration of what physical examination or careful study of history may reveal, is obliged to center the physiology and pathology of digestion in the stomach since the intestine and its tributary glands do not yield themselves so readily to systematic investigation nor to nice discriminations of therapeutics.

Within very recent times, investigators who have been able to combine reasoning with observation, have arrived at a truer conception of the relative importance of the stomach. This conception is not so satisfactory as the sweeping assertion that this organ was the mainstay of nutrition or that it was a mere accessory of digestion, since it is not adapted to unqualified statements and simple classification, nor can it be properly appreciated either by the pure theorizer or by the blind imitator of scientific technic.

The alimentary tract provides doubly for the digestion of the more important foods. Both the saliva and the pancreatic juice deal with starches, both the gastric juice and the pancreatic with proteids, all the secretions which mingle in the intestine aid in emulsifying and digesting fats. The carefulness with which mastication is carried out, the character of food, the various circumstances which tend to delay its passage through the stomach, the avidity with which the blood-vessels absorb water and dissolved solids, temporary abeyance of function, all determine differences in the precise character and the location of the digestive act.

Much attention has been given to the examination of the stomach contents after test meals and much has been learned from this study, but we must bear in mind the danger of generalizing from such observations, since the time and course of gastric digestion vary greatly with the bulk and kind of food ingested. Gastric digestion includes the complete peptonization of some proteid material. According to most writers, very little true peptone is formed in the stomach but the writer has frequently observed a slight precipitate with heat alone, a slight precipitate also with ammonium sulphate and a considerable precipitate with tannin or mercuric chlorid in the absence of dissolved starch. If this does not indicate the formation of true peptone in excess of intermediate products, the writer awaits correction. The relative amount of peptonization which takes place in the stomach as compared with pancreatic digestion in the intestine, varies inversely as the amount of food taken.

The duration of gastric digestion has not the bearing on this question which might be anticipated. Sluggish motility of the gastric wall is almost always complicated with diminished secretory power while a delay on account of a large bulk of food does not allow relatively better digestion. The notion that the stomach empties itself at a definite time after eating has been exploded; it is now known that the passage through the pylorus depends rather on the perfection of mechanical than of chemical digestion and that chyme enters the duodenum in small quantities, at short intervals. Thus, the first chyme that enters the intestine is slightly digested, the last quite thoroughly, and between these first and last consignments from stomach to intestine, the degree of digestion has gradually become more perfect. Most soluble saline constituents of food are absorbed from the stomach but water remains almost unaffected in bulk till the intestine is reached, unless extreme thirst causes unusual activity in the absorptive apparatus of the stomach. This is shown by experiments on animals. For example, a dog's intestine is severed near

the pylorus and the upper end is brought out of the abdominal wound. In this condition, the dog is almost entirely unable to slake his thirst, water swallowed issuing from the bowel, so that the poor beast continues lapping indefinitely. After small and quickly digestible meals, probably nine-tenths of the work of digestion falls on the stomach while, after a hearty mixed meal, containing an abundance of fats and vegetable fiber, it would be nearer the truth to ascribe nine-tenths of the work to the combined intestinal fluid. Such figures are, manifestly, mere approximations, nor would it be possible to imitate the normal processes of digestion by experiments in ventre nor to investigate the digestion of animals without interfering with the same normal processes.

Abandoning, therefore, the attempt to obtain a quantitative statement of the proportionate work of the stomach and pancreas in digesting proteids, we must admit that the stomach ranks in importance, somewhere between the popular belief and the modern skeptical view that it is merely a macerating and predigesting chamber. Aside from proteid digestion, the stomach is the cavity in which—though not by which—cooked starch is transformed into maltose. This change is not usually complete, from the simple fact that insalivation and mastication are rarely properly performed and, from the varying degree of acidity of the gastric juice.

Conflicting tendencies present themselves which render it almost impossible to predict the exact result of ptyalin digestion in the stomach. A light meal offers less resistance than a hearty one, but the hydrochloric acidity develops earlier and reaches a higher degree in the former case, so that there is greater inhibition of ptyalin digestion. It certainly seems that some maltose is absorbed from the stomach but it is well established that the normal completely digested carbohydrate is glucose, formed by the intestinal invertive ferment. Maltose has not been demonstrated in the blood passing to the portal system from the stomach, yet it does not accumuiate in the chyme as we should expect. The saliva, though much less energetic as a diastasic digestant than pancreatic juice, is perfectly competent to digest all the cooked starch taken at a hearty meal. Like the proteid digestion, that of starches in the stomach is necessarily very variable and incapable of quantitative estimation, in general terms.

But, whatever the relative physiological importance of the stomach, it is practically the most important part of the alimentary tract, since it can be most readily investigated and since, through it, must be directed a large share of the treatment of the other digestive organs. This statement must not be understood in the narrow sense that medicines are commonly introduced by way of the stomach. The majority of cases of intestinal indigestion are due largely to the entrance into the duodenum of undigested and irritating chyme and, until we have removed this exciting cause, by aiding gastric digestion, we are practically helpless in our attempts to modify the digestive capability of the intestine. It is true that we can get the local effect of antiseptics, astringents, and cathartics on the intestine but such drugs do not directly aid digestion, in fact many of them hinder it for the time being. Experience teaches that such medication cannot be long continued and that, on the whole, the best treatment available for intestinal disorders is the regulation of gastric digestion.

Of the two large glands contributory to the intestine, the function of the pancreas is quite thoroughly understood, but its functional diseases are unknown to us and, of the organic diseases, it is only rarely that we can recognize carcinoma, cystic degeneration, and lithiasis. The liver, on the other hand, is an organ whose physiology is still disputed or absolutely mysterious, though its gross lesions and even defects of function are fairly demonstrable during life. Here is presented the strange contrast of an organ which we understand in health but scarcely at all in disease and one which we can diagnose and treat with some satisfaction, though ignorant of its value to the body in health. In either case, depletion, stimulation, and other modifications of function are carried out by means of the stomach, by whose condition is gauged the method and intensity of treatment.

A decided difference between gastric and intestinal digestion is that the former normally proceeds with practically no interference from microorganisms, while the latter is always attended by the action of organized ferments and, in the lower bowel, true putrefaction occurs. Moreover, gastric digestion, except by the elaboration of a few organic acids during the preliminary stage of less than an hour, does not develop nor normally allows to be developed substances which are useless to the body. Pancreatic digestion, on the other hand, even if kept artificially free from concomitant bacterial fermentation, produces leucin, tyrosin and other nitrogenous substances, which are essentially excrementitious.

A REVIEW OF THE CAUSES AND TREATMENT OF ABORTION.[1]

BY W. KNOWLES EVANS, M.D.,
OF CHESTER, PA.

THE premature expulsion of the fetus in the early months of pregnancy is an event of great frequency. The number of fetal lives thus lost is enormous. There are few multiparas who have not aborted. Hager estimates that about one abortion occurs to eight or ten deliveries at term. Hirst estimates one abortion to every four or five deliveries at term. Whitehead has calculated that at least ninety per cent. of all married women, who have lived to the change of life, have aborted. The influence of this incident on the future health of the mother is of great importance. It rarely indeed proves fatal, but it often produces great debility from the profuse loss of blood accompanying it, and it is one of the most prolific causes of nervous and uterine diseases in after life, possibly because the women are more careless during convalescence than after delivery, and the proper involution of the uterus is thus more frequently interfered with.

By the term "abortion," in this paper, I wish to be understood to refer to the expulsion of the ovum before the fourth month.

Among the usual causes of abortion are: (1) Death of the fetus; (2) abnormalities and diseases of the membranes, including the decidua; (3) apoplexies of the ovum; (4) traumatism; (5) diseases of the mother directly affecting the product of conception (as syphilis); (6) The fact of the mother having previously aborted; (7) irritable uterus (the expulsion in such cases results from a trivial cause, as a long walk, purgatives, jolting, congestion of the pelvic organs, chronic constipation, reflex irritation, as from suckling; extraction of a tooth, pruritis, ovarian disease, etc.; these causes are most liable to produce abortion at the menstrual epoch); (8) spasmodic muscular action in the mother, as chorea; less than half the cases going to term, the premature expulsion of the ovum being explained by physical exhaustion, blood stasis and CO_2 in the uterine muscle, stimulating it to contraction, or by choreic movements in the uterus itself; (9) uncontrollable vomiting and coughing; (10) epileptic, hysterical, cholemic, and tetanoid convulsions; (11) poisons of all the infectious fevers; (12) certain local conditions cause abortion, as tubal or ovarian disease, perimetritis and adhesions, fibroids and polyps, uterine displacements, laceration of the cervix in irritable uteri, previous overdistention of the uterus from hydramnion or multiple pregnancies; and finally, as rare causes, might be placed obesity and contagious abortion, the last being really cases of septic infection (Hirst).

The clinical phenomena present hemorrhage, pain, expulsion of some portion of the ovum. All three are rarely typically manifested in every case. Their duration varies from an almost instantaneous act to days or weeks. In *early* abortions, hemorrhage is more pronounced than *pain*, and the blood is extruded in coagula. The appearance of the substance expelled varies with the period of pregnancy and the entirety of the product of conception. The coronal coat may be entire, the decidua alone may surround the embryo, or it may be surrounded by the amnion. Most frequently the decidua vera remains behind, and hence the danger of sepsis.

In regard to the mortality of abortions, out of 926 cases noted by Hirst, there were 13 deaths—a mortality of 1.4 per cent.

The diagnosis of threatened abortion would be made in a case where we had hemorrhage and more or less pain in a patient, with signs of early pregnancy. The diagnosis of inevitable abortion would be made from persistent hemorrhage, dilatation of the os, ovum presenting, considerable pain and effacement of the angle between the upper and lower segments. Exceptionally one or more of these may be present and the case go to term. The diagnosis of incomplete abortion is made by examining carefully the fragments discharged by floating them in water. Here the digital examination will usually find the os patulous and detect shreds of decidua, the placenta, or fetal membranes in the uterine cavity. The diagnosis of complete abortion is made by the uterus being firmly contracted, the os retracted, and examination of the uterine cavity difficult or impossible. Here the diagnosis must depend largely on the *history* of the case, the examination of the discharge, the enlarged uterus, lochial discharge, and finally the disappearance of the presumptive signs of pregnancy, which had previously existed. Inevitably the ovum must be destroyed. Retained fragments may develop into polypi. The dangers to the woman are hemorrhage, particularly the secondary effects, and sepsis.

The preventive treatment includes the causes that may exist in any case. Enjoin rest at the menstrual epoch, and restrain sexual intercourse where there is an irritable uterus. Replace a displaced uterus; repair a lacerated cervix; treat

[1] Read before the Delaware County Medical Society, June 19, 1896.

any inflammatory condition about the uterus. In threatened abortion, the treatment is absolute rest in bed, drugs to diminish nervous sensibility and muscular action, as opium, potassium bromid, and chloral. Opium should be given in full doses, by the mouth, hypodermatically, or by the rectum. The fluid extract of viburnum prunifolium, in dram doses, is very efficient. It may be combined with opium, administering the latter by suppository. In inevitable abortion, the treatment is as follows: If the hemorrhage is profuse before dilatation of the os occurs, control the bleeding by vaginal tampons of antiseptic wool or baked cotton. Remove in eight hours and reapply if required. Often when the first one is removed the ovum is found extruded, when the urgent symptoms may subside (Hirst). The plugging of the vagina may be done in various ways. The tampon may be made of a long strip of aseptic or antiseptic gauze, or of pledgets of cotton (antiseptic absorbent) or wool, or, in the absence of these materials, of any soft fabrics, such as a silk handkerchief, a soft towel, or strips or pieces of sheeting, cheese-cloth, an ordinary roller-bandage, etc. Whatever material is used, it is understood that it must be thoroughly sterilized by boiling, by dry heat, or by steam, or it may be scalded thoroughly in some hot antiseptic solution. If a large number of pieces are used, they should be secured together by a string, so as to facilitate their withdrawal. More accurate tamponing can be done when the tampon is dry than when it is wet. For introduction of the tampon, the patient should be placed across the bed or, better, on a table, in the dorsal or Sims' position, with the hips at the edge of the bed or table. A very copious hot water or hot antiseptic vaginal douche should next be given, after the bladder has been emptied. The tamponing may be done with the aid of a Sims' speculum, if assistance is at hand; if not, then a bivalve speculum may be used, or as some prefer, one or two fingers are introduced into the vagina, and there act as a guide. With dressing forceps one end of the strip of gauze or a pledget of the tamponing material is passed into the vagina along the introduced fingers and is accurately packed by them into, against, and about the os and the cervix. The tamponing should be continued in this way until the vagina has been moderately filled. Moderate doses of the fluid extract of ergot should be administered every two or three hours, together with quinin or strychnia where these are indicated for debility. If there is much pain, five-grain doses of phenacetin will give the patient comfort without interfering with uterine contraction (Etheridge).

In these cases the deciduous membrane in the early months, and the placenta in the later, are apt to remain behind. The best method to employ for their removal is a disputed question. Riviére states in every case, "If there is no complication, do not hasten; let there be no untimely exploration—simply expectation, rest, and antisepsis. If complications occur, the treatment must be active." Hirst[1] teaches the following: "The expectant plan combines the use of ergot, the tampon, and great care to avoid rupturing the membranes. If the abortion be incomplete, rest in bed, small doses of ergot, vaginal and, if possible, intrauterine douches of antiseptic solutions. *At the first sign of sepsis, the uterine cavity should be cleared out.*" The active plan of treatment, which is better, involves the use of the tampon to control bleeding, and the removal of the contents of the uterus by the finger (rendered thoroughly aseptic before using), or, in experienced hands, the curette, after which an intrauterine douche of a two per cent. solution of creolin should be given. If needed, Hager's dilators may be used to stretch a retracted os.

Very little after-treatment is required beyond confinement in bed until involution is complete. When the expectant plan has been followed, antiseptic douches are to be used and the earliest indications of sepsis looked for.

Riviére, in cases of septicemia, when the disease has been early recognized, uses antiseptic vaginal injections, morning and evening, and employs powdered iodoform upon the vulva, and the occlusive dressing with aseptic cotton, secured by a T bandage. If, after careful antisepsis and the free use of quinin, the fever does not abate and chills recur, he again employs the curette. After all cases of curetting, whether digital or instrumental, he injects Churchill's tincture of iodin.

Warmann uses asafetida with good results in "abortio-habitualis." He uses the drug in pill form, commencing with two a day and increasing to ten, subsequently reducing.

The plan advised by ancient writers of employing phlebotomy in cases of threatened abortion has been successfully used by Viscaro. He draws one or two ounces of blood from one of the veins of the hand. He cites a number of cases where the symptoms of abortion have subsided and the pregnancy continue to term.

CLINICAL MEMORANDUM.

CYST OF THE BRAIN IN THE FOOT OF THE LEFT SECOND FRONTAL CONVOLUTION; MOTOR AGRAPHIA (?) FROM INABILITY TO SPELL; EVACUATION OF THE CYST; IMPROVEMENT; TRAUMATIC MENINGEAL HEMORRHAGE TWO MONTHS LATER; SECOND OPERATION; RECOVERY.

By J. T. ESKRIDGE, M.D.,
OF DENVER, COLO.;
NEUROLOGIST TO THE ARAPAHOE COUNTY AND ST. LUKE'S HOSPITALS,
AND
CLAYTON PARKHILL, M.D.,
OF DENVER, COLO.;
PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF COLORADO; SURGEON TO THE ARAPAHOE COUNTY AND ST. LUKE'S HOSPITALS; CONSULTING SURGEON TO THE STATE INSANE ASYLUM; SURGEON GENERAL OF THE COLORADO NATIONAL GUARDS.

MR. W. E. F., white, aged thirty-four, born in Pennsylvania, married, stock raiser by occupation; resident of Colorado nineteen years, first consulted me April 18, 1895. Father is living and well, mother was subject to "sick headache," and died of "brain fever"; two brothers are living and in good health, except that they suffer from "sick headache"; one aunt is also similarly affected. There is no epilepsy, consumption, insanity, or alcoholism in the family.

The patient as a child was strong and rugged. At his twelfth year he suffered from an attack of measles. At the tenth or twelfth year he began to be subject to severe headaches. They would occur every two or three weeks and pass off after several hours' sleep. The attacks seemed to be brought on by exposure, exhaustion, overeating or some indiscretion in diet: The pain came on suddenly, was sharp, dull or aching in character, and located chiefly in the right temporal region. After several hours, the patient would vomit one or more times, fall asleep and awaken free from pain. As maturity was reached the attacks lessened in frequency and severity, and during the last five years he has experienced only a few seizures each year, the number depending apparently upon irregular habits and indiscretions in eating. He has not been addicted to frequent or excessive use of alcohol. During his twenty-second year, subsequent to exposure to cold, he suffered from severe pain in the left ear. Ten days after the pain commenced, a purulent discharge began from the external auditory meatus of this ear, and continued for three weeks. Six years later he had an attack of la grippe, which was followed by a purulent discharge from the same ear, that ceased after two weeks. Since then his hearing has been lessened in the left ear, and he occasionally experiences a throbbing sensation in it. Five years ago he contracted syphilis, but no secondary symptoms followed. The patient has suffered from indigestion for some years. The symptoms of this have been heartburn, pyrosis, eructations of gas, and distress after eating.

In 1892, one year after his marriage, his wife observed that he was becoming very jealous of her. He would become enraged if he saw her talking to her own brother. After his explosive fits of jealousy, for which there seemed to be no cause, or even the suspicion of one, he would tell his wife that he did not mean what he had said. His jealousy concerning his wife increased, and sometime in 1893, while she was lying in bed with him one night, he tried to choke her. She broke away from him and asked him what he meant. He smiled and said he was only playing. She at that time noticed no other evidence of mental deterioration, except that he was becoming more irritable. In September, 1893, he first experienced difficulty in writing. Before this he had been a good and rapid penman, having served as bill clerk in the house of representatives during two sessions of the State legislalature. The difficulty in writing consisted in misspelling and in transposing the letters of the words. The disturbance soon became so great that it was difficult to make any sense out of what he had written. He had been before his illness fairly good in spelling, but at times was careless. Scarcely a word of any length was spelled correctly a year after he began to experience difficulty in writing. He soon ceased to write as the effort was tiresome to him and he had to spend an hour or more in trying to write a page of note paper. In February, 1894, he suffered an entire night from severe, sharp, shooting pains in the chest in the region of the heart. The attack gradually subsided the next day, but he was left weak and very nervous. He has not had so severe an attack of this since the first one, but every few weeks, since the occurrence of the first, he has experienced sharp and shooting pains in the cardiac region.

In July, 1894, the patient began to suffer from pain in the frontal region. In character this resembled the cardiac pain which he had experienced some six months before. After July, 1894, the head pain became quite frequent, occurring every two or three weeks, sometimes every few days. The pain lasted for a few hours and disappeared after a few hours' sleep. He did not feel nauseated at the time, nor did he vomit. During the paroxysm he frequently found some relief on closing his right eye.

Three months before consulting me, or about the middle of January, 1895, while the patient was conversing with his wife, he suddenly found himself unable to talk for fifteen minutes. He could not utter a single articulate sound. He says that his mind was perfectly clear at the time, and he thinks that he could have written what he wanted to say, had he not been so nervous. He, however, made no attempt to write. Gradually his power of articulation returned and within fifteen minutes after he was first able to speak, he could call his wife's name, and frame a few sentences connectedly. An hour later all speech disturbance had passed away. Since January the patient on four or five occasions has experienced difficulty in speech which came on suddenly, but at no time has there been a total inability to speak, as in the first attack.

Between the seizures of speech difficulty the patient often shows hesitancy in speaking, but, as a rule, he could talk quite well. He says that since January he has had difficulty in remembering proper names, and occasionally has used a wrong word when he knew well the word that he wanted to employ.

Six or seven weeks ago he experienced a peculiar visual disturbance. He says it appeared to him as though he was looking into a tunnel. Outside of his central vision everything seemed hazy and indistinct. His expression was: "It looked to me as though my central vision was surrounded by clouds of steam." The defect in vision lasted for about half an hour, and it has recurred twice since. Yesterday the patient experienced some temporary blurring of vision. It came on suddenly and disappeared rapidly after it had lasted for a few minutes. The difficulty in writing, which was first observed about eighteen months ago, has continued; and this morning he suffered from the frontal pain for one hour.

Examination April 19, 1895.—Physically the patient looks, and says he feels, strong and well. He is unusually well developed and strong. He experiences much less trouble with his stomach than he formerly did. Gait perfect, no ataxia, no paresis, or paralysis of any muscles. Dyn. R., 236; L., 210. All the deep reflexes about normal except that the knee-jerks seem a little lessened; the reflexes of the right arm are all a little greater than in the left. All the superficial reflexes are present except the cremaster, and their absence can be accounted for by the presence of a double inguinal hernia, which has existed for a number of years. A fine tremor at times is observed in both arms. It is said to come on after exertion and is more marked in the left than in the right arm. All general sensory phenomena are normal. Taste and smell are present and equal. Hearing: Watch, R., 10/12; L., 9/12. Tuning fork is heard a little more distinctly in the left ear. Vision in each eye, 6/9; fields normal, both for light and color; pupils normal in size and react readily to light and accommodation. External ocular muscles act well. Fundi and disks show no pathological change. Slight refractive error. Mental action slow with lessened power of mental concentration, sustained attention, and memory. There is no form of visual or auditory defect in speech. The receptive centers concerned in speech memory seem to act normally. On testing the motor or emissive side of speech, it is found that he can speak voluntarily, but that speech is a little slow, and he occasionally hesitates in pronouncing long words. He repeats words after another quite readily, except that he is slow and deliberate in articulation, and sometimes he hesitates before trying to utter some words. It is observed that the greater the effort he makes in trying to utter a word, the more nearly he succeeds. If the patient makes a mistake he at once recognizes it and usually corrects it. He has no difficulty in thinking in speech. I am unable to discover any special difficulty in the use of any part of speech. He understands and uses gesture expressions in speech. On testing his ability to write a peculiar defect is found. He writes his name perfectly and copies script and printing into script with scarcely a mistake. In writing voluntarily he transposes the letters of a word, adds and omits letters, so that what he writes makes very little sense unless one knows what he is trying to say. On requesting him to spell words it is found that he spells the words just as he writes them. It seems to matter but little how he spells a word, he usually pronounces it correctly. The thoracic and abdominal organs appear healthy.

The pain of which the patient had complained during the last few months had been referred to the right frontal region, but the more reliable localizing symptom, the disturbance in speech, especially inability to write, the so-called agraphia of the motor variety, pointed to the left frontal region as the seat of some organic brain disease. The opinion was expressed that a tumor was forming in the motor speech center, and affecting more particularly the foot of the second frontal convolution. He was placed upon increasing doses of potassium iodid, requested to remain in town and report once or twice each week. He returned home, a distance of about fifty miles, a day or two later, took the medicine irregularly for a short time, but not improving, he soon discontinued its use entirely. I did not hear from him again until October 24, 1895, about six months after he had first consulted me.

During these months he suffered nearly constantly from dull heavy pain on both sides of the head in the frontal region. He also experienced about twice a week severe paroxysms of acute pain. During these attacks the pain was located in the frontal region, but always worse on the left side, and most intense in the anterior and upper portion of the temporal fossa. The paroxysms usually occurred during the latter part of the day or early evening, and passed away after sleep, as before noted. Their occurrence seemed to be due to exposure to the sun's rays, over exertion, or excitement. Occasionally an attack would be mild, but the next one would be very severe. During the time the pain was most severe, the scalp over the anterior portion of the head, but more especially over the left side, would become sensitive to pressure. His speech disturbance increased, and he became more irritable and forgetful.

On October 24, 1895, I was hastily summoned to see him at his home, in consultation. In addition to the facts already stated, I learned from his wife that his eyes had not troubled him much since I was consulted, except that occasionally the peripheral fields of vision would become blurred for a few minutes. About May 15, 1895, she observed that her husband did not walk as well as formerly, and six weeks ago he manifested a tendency to go to the left in walking, and would frequently trip because his feet were not raised sufficiently high. He had not been able to dance as well as formerly. There had been for sometime an awkward movement of his hands, and in reaching after things his right hand would close before the objects that he intended to grasp were approached. The patient had become quite nervous, and his power of mental concentration and sustained attention were much lessened. His memory for recent events was very poor, but for those of early life it was unimpaired. He had lost considerable in weight. On two occasions when he was suffering from severe headache, he had projectile

vomiting, and seemed to be almost unconscious for several hours each time. Six days before I was summoned, he began to suffer from a paroxysm of severe headache. After it had lasted several hours, he lost his power of speech for two or three days. He seemed in a semi-conscious condition, lay in bed and took little notice of things if not disturbed. He could be aroused and his attention engaged for a short time, but he seemed dazed. He complained of his right arm feeling numb as he began to regain consciousness. When I saw him there was no paresis or paralysis of any muscles; the eyes showed no change in central vision, fields, fundi, or disks; and all forms of general or special sensations, so far as I was able to determine, were normal.[1] He seemed weak and dazed, and apparently not completely realizing what was going on around him. He made no complaint of anything when left alone, but when I asked him is he had any pain he said "yes," and placed his hand on the left side of the forehead. On percussing the head on both sides, I found an area of tenderness about an inch and a half in diameter, situated on the left side just above the speech center of Broca. He was disinclined to talk, and no attempt was made to test his powers of speech at this time. At my request he was transferred to Denver the same day and placed in St. Luke's Hospital. After putting the patient in the Hospital, he was tenderly nursed, careful and repeated bilateral axillary temperature observations were made, and a record was kept of everything likely to throw any light on the case. The temperature was about equal in each axilla, and usually about .5° below normal. The pulse varied from 72 to 82; respiration from 16 to 24, but it usually remained at about 18.

October 27th: His gait is firm, but there is a little tendency for the body to reel on first closing his eyes while standing, but this passes away in a few seconds. The right hand, while not distinctly ataxic, is used more awkwardly than the left. Dyn. R., 224; L., 200. All leg and arm muscles are strong. A slight tremor is observed in the right hand when he grasps anything very firmly. It is thought that the right thumb and index finger are flexed and extended a little more slowly and awkwardly than the left. He can flex and extend the left index finger without allowing the hand to move at the wrist, but in flexing and extending the right index finger the hand invariably moves at the wrist, although he tries to prevent it. The muscles of the right side of the face appear a little weaker than the left, but the difference is very slight. The tongue deviates slightly to the right in extreme protrusion. There is no wasting of any muscles. Both knee-jerks are a little increased over the normal, the right more than the left, and are decided on reinforcing. Ankle-clonus absent. Tendo-Achillis, R., decided; L., slight. Plantar and cremaster reflexes are absent. Lower abdominal, present; epigastric, R., absent; L., present. The deep reflexes of the arms are increased. There is no trouble with the sphincters of the bladder or bowel. General sensory phenomena are nearly normal. On the lips and tongue on the right side he readily feels the contact of a substance, but two points of the esthesiometer are not differentiated at twice the normal distance. He is unable to localize a substance in gentle contact with the right hand as definitely and quickly as he can with the left. Smell and taste are acute on both sides. Hearing R., ⅗; L., ¼. The tuning fork is heard better in the right ear, even when the left is closed. Central vision, fields, for both light and color, fundi and disks normal. There is an area about one and a half inches in diameter over the left frontal region, in which percussion and firm pressure cause him to wince from pain. The lower border of this area is bounded below by the Sylvian line, posteriorly by the ariculo-bregmatic line, and anteriorly by a vertical line extending upward from the external angular process of the frontal bone. No change in the percussion note is detected over the sensitive area. There is no tenderness over the corresponding portion on the right side of the head. His mind acts slowly, but he reasons fairly well and his conclusions are usually accurate. He laughs, jokes, and seems contented.

On making a systematic examination into the condition of his speech defect, no auditory or visual speech disturbance is observed. There seems to be no form of sensory aphasia. His answers are slow and he has difficulty in selecting his words, but he almost invariably gets the right one. He frequently omits the last syllable of a word, and sometimes one or more words of a sentence. He has no difficulty in thinking in speech. So far as speech-utterance is concerned, there is a slowness in selecting a word, a hesitancy in uttering it after it has been selected, and some difficulty in pronouncing long and difficult words. He repeats simple words after another quite rapidly and without the least hesitation, but if he has to select these same words in conversation, the task is laborious and is performed slowly. He reads aloud writing and printing quite readily, but not infrequently omits and miscalls words. He says that he has no difficulty in understanding what he reads. Writing is the most difficult task for him to perform. He writes his name slowly and distinctly, but it is not written in the bold, easy hand in which he formerly wrote it. His writing seems so remarkable that I determined to study its defects thoroughly. A business letter written by the patient in March, 1894, was written in a distinct and easy hand, although this was written six months after he first experienced difficulty in writing. There were no errors in spelling, and the letter was connected throughout. On obtaining short letters that he had written to his wife during the six months previous to October, 1895, while he was in Denver or different portions of the State, attending to business, I find that, although nearly every letter was well-formed, the spelling was so bad, so many letters were omitted or added, while others were transposed, that I am unable to read his writing. On asking him to read these letters, he reads portions of them, but supplies words. One curious fact is that, no matter how awkwardly a word is spelled, he usually pronounces it according to what he had meant to write. I notice that to few of the letters that he had written during the past six months had he attached his

[1] At first I thought that tactile sensation was lessened over the right hand, but the mental impairment of the patient was too great to enable me to determine this point satisfactorily.

name. This seems strange, as he can write his signature without much difficulty. In writing simple words, such as "dog," "cow," "hog," at dictation, he frequently transposes some of the letters, and is as long in writing a single letter as a child is when it is first learning to write. He can write voluntarily, but it requires about two hours for him to write five or six lines. He can read much of what he has written, but miscalls words, inserts some, and leaves out others. When he makes a mistake in writing he sometimes recognizes it and will try to correct it, but he frequently makes a greater mistake in trying to correct one. At other times he is either indifferent to his mistakes or does not perceive them. The effort of writing is very exhausting on him. He can copy fairly well, transcribing both printing and writing into script. On getting him to spell a word aloud, he always spells it just as he writes it, although in either case he pronounces it correctly.

October 28th: On his admission into the Hospital, the 24th inst., blue ointment was ordered rubbed in night and morning, and he was given potassium iodid in increasing doses. He is much brighter and his headache is much less. It has been observed that he magnifies trifles and delights in talking about little things that relate to himself. He talks much better.

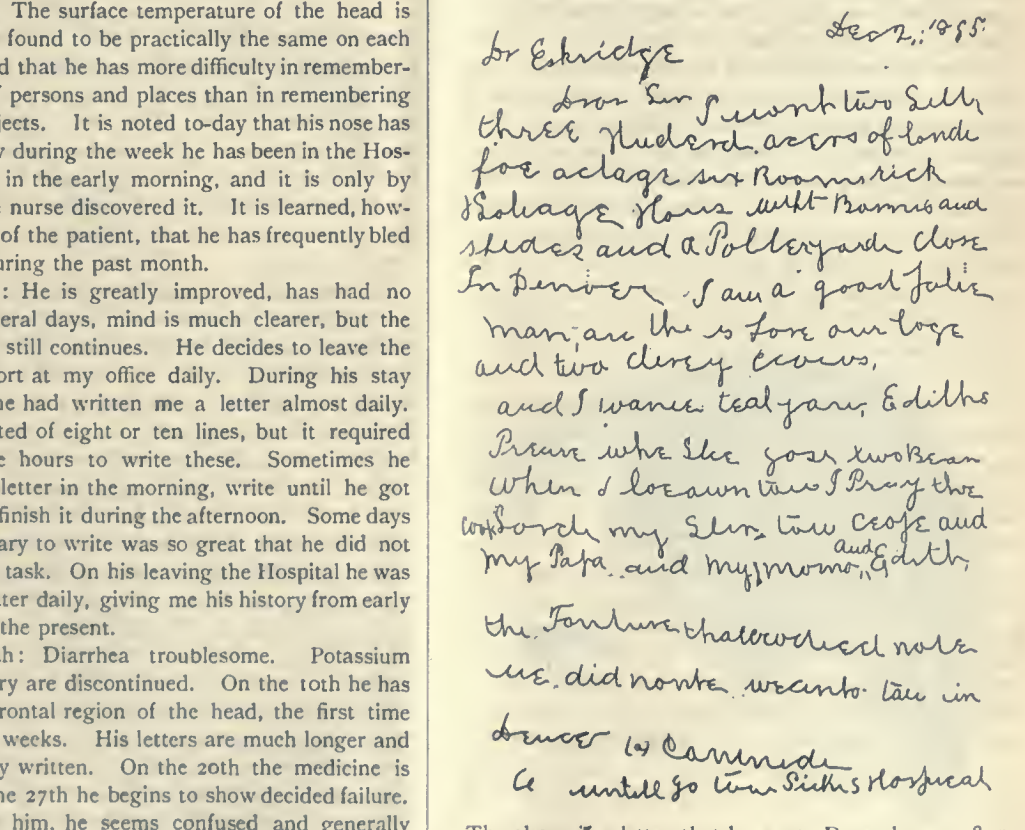
October 30th: The surface temperature of the head is registered and is found to be practically the same on each side. It is found that he has more difficulty in remembering the names of persons and places than in remembering the names of objects. It is noted to-day that his nose has bled almost daily during the week he has been in the Hospital. It occurs in the early morning, and it is only by accident that the nurse discovered it. It is learned, however, on inquiry of the patient, that he has frequently bled from the nose during the past month.

November 3d: He is greatly improved, has had no headache for several days, mind is much clearer, but the defect in writing still continues. He decides to leave the hospital and report at my office daily. During his stay in the Hospital he had written me a letter almost daily. It usually consisted of eight or ten lines, but it required him two or three hours to write these. Sometimes he would begin his letter in the morning, write until he got tired, stop, and finish it during the afternoon. Some days the effort necessary to write was so great that he did not feel equal to the task. On his leaving the Hospital he was to write me a letter daily, giving me his history from early childhood up to the present.

November 7th: Diarrhea troublesome. Potassium iodid and mercury are discontinued. On the 10th he has pain in the left frontal region of the head, the first time for nearly two weeks. His letters are much longer and more connectedly written. On the 20th the medicine is resumed. By the 27th he begins to show decided failure. His head pains him, he seems confused and generally discouraged.

November 28th: He says that he was unable to write me his usual letter this morning, on account of headache and dizziness. The tongue deviates decidedly to the right, but there is no apparent paresis of the right side of the face. It is almost impossible to understand him, as he utters words so indistinctly. With an effort he can read aloud so as to be understood, but he substitutes, transposes, and omits so many words that what he reads does not make much sense. He says that he is nearly crazed with pain. Both optic nerves are pale, or almost white, and apparently show beginning atrophy, but vision and fields remain nearly normal. He is given something to relieve his pain and told to keep quiet for the day.

December 1st: He looks pale and distressed. It is impossible at first to quiet him. He wrings his hands and groans as if in great mental or physical distress. After awhile he tells me that he had not slept any the previous night, and had cried most of the time. He says that his distress was not on account of pain, but because he had revealed to me in his letter of the day before the password of the Woodman's Lodge, and he is fearful lest he will be placed in the penitentiary for it. It is some time before I can convince him that he has written nothing of the sort, and this can be done only by showing him two or three of his previous letters. He then comes to the conclusion that he must have been insane all night. On my advising an immediate operation for the relief of his brain trouble, he readily consents, and seems happy in the prospect of relief.



The above is a letter that he wrote December 2, 1895, three days before the operation. It seems to admit of the following liberal translation:

"December 2, 1895.

"Dr. Eskridge:

"Dear Sir: I want to sell three hundred acres of land for a

house, a six-room brick cottage, with barn, sheds, and poultry-yard, close to Denver. I am a good poultryman. We have four cows, two large and two small dairy cows. I want to tell you Edith's prayer, which she says when she goes to bed, 'When I lay me down to sleep, I pray the Lord my soul to keep and my papa and my mamma, and Edith and whom I love as my own soul.' The furniture that we do not want in Denver I wish to sell. Continued. Until I go to St. Luke's Hospital."

FIRST OPERATION AND SURGICAL ASPECT OF THE CASE.

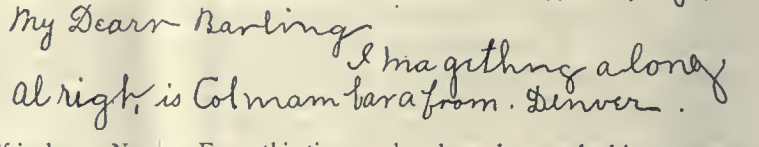
BY DR. PARKHILL.

Operation, December 5, 1895, 11 A.M. The usual methods had been observed in preparing the scalp for operation on the previous day, including the outlining of measurements in nitrate of silver. At the time of the operation these measurements were transferred to the skull by means of the Parkhill skull-marker. A semi-circular flap with the base downward was raised and a three-fourth inch button of bone was removed from over the region of the foot of the second left frontal convolution. This opening was enlarged with the rongeur until it had a diameter of about one and a half inches. No pulsation was preceptible either to sight or touch and the dura bulged irregularly into the wound. Across the middle of the exposed surface of the dura there was a constricted band-like appearance running from before backward, which held the dura below the surrounding portion of the exposed membrane. On endavoring to relieve the constriction by cutting through the dura at this point, which was found to be very thick, a straw colored fluid spurted out several inches high, apparently from the substance of the brain. The opening through which the fluid escaped was now enlarged, and about an ounce of fluid in all was found. The cyst which had contained the fluid was situated immediately below the cortex and extended into the brain substance to the depth of half an inch or more. The globular portion of the cyst lay within the white substance of the brain, the constricted neck-like portion in the cortical, and its external boundary was formed by the membranes of the brain. The fluid was watery, straw colored and contained no pus- or tumor-cells. A small rubber drainage-tube was inserted into the cyst cavity and brought out through the middle of the scalp flap. The dura was sutured with catgut, the scalp with silkworm-gut, and the ordinary antiseptic dressing was applied. But little shock resulted from the operation, and the recovery from a surgical standpoint was perfect. On the ninth day the head was dressed and the cavity was apparently almost obliterated. On December 15th, the scalp was raised and gold foil placed between it and the dura, there was practically no reaction from this and his recovery was uneventful.

CONTINUATION OF THE RECORD.

BY DR. ESKRIDGE.

December 5, 11 P.M., about eleven hours after the operation, he is feeling quite comfortable, except a little nauseated. The right lower side of the face is partially paralyzed and the tongue deviates to the right in extreme protrusion. Motor disturbance in speech very marked, but he is still able to think in words and utter a few voluntarily. He can repeat simple words after another. Two days after the operation, the paresis of the right side of the face had passed away, and he could articulate more distinctly than he could immediately before the operation was performed. December 8th. He is still improving and utters long and difficult words quite well. On the 10th he attempted to write, and while he formed his letters distinctly, no sense could be made of what he had written because of the bad spelling. On the 11th his attempt at writing was still a failure. On the 12th he spent about an hour in writing his wife the following:

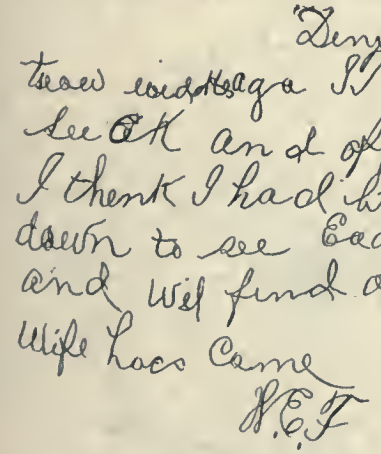


Denver Colo
Dec. 12, 1895—
My Dearr Darling
I ma getting along
Al right, is Colmam bara from. Denver.

From this time on he showed a gradual improvement in his writing. On December 30th, he copied several lines of writing, and a paragraph from a newspaper, an extract from a political speech, all into script with scarcely a mistake. On the 31st he wrote me a letter of fourteen lines. It was written connectedly, and is easily read, but there are several gross mistakes in spelling, and a few letters are transposed. Every letter is well formed. During January he wrote me a letter about every second day. The letters are written connectedly, and are comparatively easily read.

February 1st, he struck his head against a wooden box, the sharp corner of the box striking the head at the point where the bone had been removed. The next day he began to suffer from frontal headache, felt dizzy, was nauseated, and vomited. On the 3d and 4th he was quite drowsy, and complained of a numb sensation in the right hand and arm. The hand felt so lifeless that he could not find his pocket with it, unassisted by vision. His vision soon began to fail, he lost flesh, and suffered almost constantly from headache, nausea, and vomiting. It was observed that he was extremely forgetful, and acted foolishly at times. On the 12th he came to Denver and I made a careful examination into his condition. He had lost considerable flesh, looked haggard and depressed. He was suffering greatly from pain in the left frontal region of the head. He was weak, but there was no paralysis of any muscles. The only change in the deep reflexes was an increase of those of the arms. Nearly all the superficial reflexes were absent. All general sensory phenomena normal, except localization and muscular senses. Localization was considerably lessened in the right hand and slightly in the left. Muscular sense was lessened in the arms and hands, but very much greater on the right side than on the left. His mind was much confused, and he did not seem to be able think clearly or

connectedly. Hearing, smell, and taste appeared nearly normal. Central vision, with the right eye, was 4/6; left, counts fingers at eight feet. It was impossible satisfactorily to test the fields on account of his mental confusion. There was well-marked atrophy of each optic nerve, much more pronounced in the left eye than in the right. The arteries of the left disk were very small, but those of the right were nearly normal in size. The letter that he wrote me on February 4th, three days after the injury, did not contain a legible word. A few letters were well formed, but most of them were meaningless scrawls. Meningeal hemorrhage was suspected, and an immediate operation for the relief of pressure on the brain was urged. He was placed in St. Luke's Hospital and operated upon by Dr. Parkhill the following day. On completing the examination on February 12th, I requested him to write me a short letter, and to my surprise he wrote more connectedly, and with fewer errors, than he had been able to do before the first operation. It is given here:



In this letter he tried to say that he was taken ill two weeks ago on Wednesday, "and I was awful sick. I think I had better go down to see Ed Lewis and will find out if my wife has come."

Most of the letters are well formed, and his own name is written in a bold hand, but only the initial letters of his signature are given for obvious reasons.

SECOND OPERATION.

By Dr. Parkhill.

On February 13th, it became necessary to operate upon him again. The preparation was the same as for the preceeding operation, excepting only the outlining of the scalp. On dissecting up the former flap the gold foil was found in position, and it had perfectly prevented the formation of adhesions between the scalp and the dura. Therewas no pulsation. On opening the dura, at the seat of the former cyst, the brain substance had nearly a normal appearance.

The opening in the skull was then enlarged upward and forward. When a half inch of the bone had been taken away, and the dura opened correspondingly, it became apparent that there was a cyst, or membranous-like substance, under the dura. The opening in the skull was further enlarged upward and forward, until it had a diameter approximately of 2½ inches, and the dura incised accordingly. This did not reach the limits of the false cyst. It had a muddy-yellowish appearance and distinctly fluctuated on palpation. The trocar and cannula were passed into it, and there was withdrawn about half an ounce of sero-sanguineous fluid. The cyst was then freely opened with a knife and, upon exploration, it was found to contain quite a quantity of blood clots, perhaps one ounce. It was apparently a closed sac. I then began the dissection of the sac from its seat, by means of the fingers and forceps, and found it extended almost completely over the frontal lobe, reaching down as far as the floor of the anterior fossa of the skull, and dipping into the anterior extension of the middle fossa in the region of the fissure of Sylvius. Internally, it was attached to the falx cerebri. It extended backward over the Rolandic region and the parietal lobe as far as I could reach with the finger and forceps. It was friable, and complete dissection was made only with the greatest possible care. When this was removed, the cortex at its site appeared flattened and depressed to an extent of about half an inch, the brain did not expand after the removal of the cyst-like membrane.

Considerable capillary hemorrhage was encountered during the removal of the false cyst, but this was readily controlled by means of gauze packing and pressure. The cavity was drained, the dura sutured, and gold foil was placed over the dura, leaving only a small opening for the drainage-tube which was brought out through the scalp. The scalp was then replaced and the ordinary dressing applied. Very decided shock followed this operation for the first few hours, but active stimulation overcame this and his progress toward a surgical recovery was uninterrupted. Apparently, however, the brain never regained its normal dimensions, as a decided depression remains at the site of the operation to this day.

CONCLUSION OF THE RECORD WITH REMARKS.

By Dr. Eskridge.

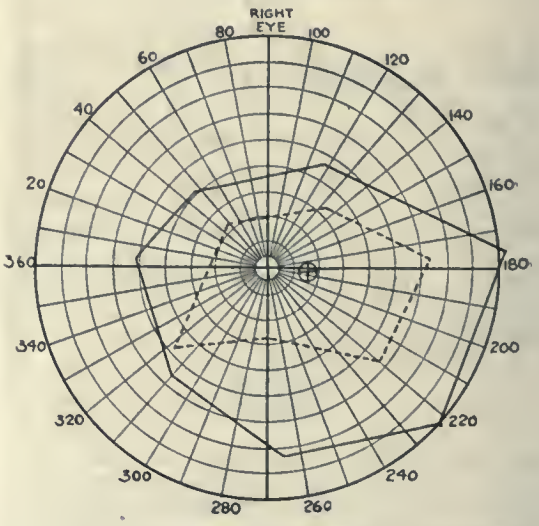
After the second operation he had five or six convul-

The light circle represents the size of the opening in the skull after the second operation. The dark-shaded area near the anterior border of the circle indicates the extent of the opening made at the first operation. About the center of the dark-shaded area the cyst was found.

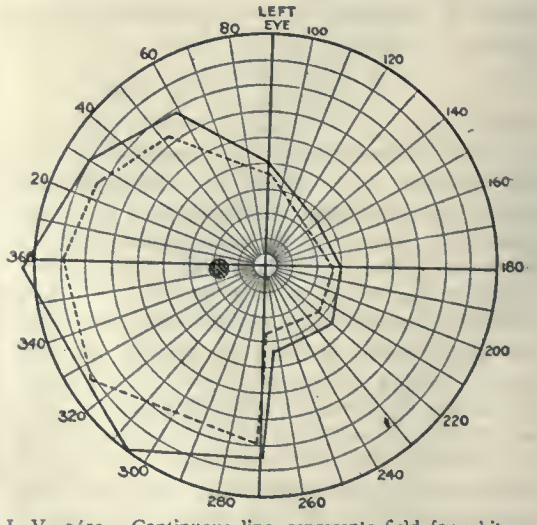
sions, all beginning in the right hand and most of them limited to the right hand, arm, and face, the right leg being involved only on one or two occasions. The left side was not affected. These convulsions began two or three days after the operation, and one and sometimes two occurred on the same day. With the exception of these attacks little of interest from a neurological point was observed until March 6th, nearly four weeks after the operation, when he was able to resume his letter-writing. On that day he spent nearly an hour in trying to write me a letter. The result was: "Elbert, Colo., 6, 1896. My Dear. I Sind." All the letters were well formed. During the afternoon of the same day he wrote me six lines, but with the exception of my name, not a single word is legible, although all the letters are well formed. He had considerable difficulty in articulation at this time, but he seemed to be able to think in speech, and slowly repeat simple words after another. About this time he manifested almost an insane jealousy of every one who spoke to his wife. Although he wrote me a letter almost daily, it was not until the 14th of March that a single legible word was found in them, if the headings of the letters are excepted. From this time on he showed considerable improvement in his writing and speaking. It became evident as time wore on that he was partially demented.

April 14, 1896: There was a slight uncertainty of gait, especially when the eyes were closed, with a tendency to walk to one side, sometimes to the left, at other times to the right. There was slight ataxia in the arms; none in trunk muscles. No paresis or paralysis of any muscles. Dyn. R., 190; L., 184; a decided improvement since the last operation. Knee-jerks, R., about normal; L., decidedly lessened; ankle-clonus absent. Plantar reflexes, R., absent; L., slight. Tendo-Achillis, R., present; L., absent. Deep reflexes of arms slightly increased, a little more on the right side than on the left. All general sensory phenomena normal. Muscular and localization sensations, which had been deficient in the right hand and arm before the second operation, were apparently as good as in a healthy person. Hearing, taste, and smell, presented no points of interest. Eyes, R., counts fingers at eight feet; L., counts fingers at two feet. Roughly testing fields, those of the right eye for objects seemed fairly good, but lessened for color, especially for red, etc. The fields of the left eye were all abolished except in the lower quadrant of the temporal side. The pupils reacted to light and accommodation and all the external ocular muscles were normal. Both disks presented whitish atrophy. The capillaries had disappeared, and both arteries and veins were less than the normal size, the arteries being exceedingly small. It should be noted that at no time had the disks presented an edematous appearance. On making a systematic examination into the condition of his speech no sensory defect was found. He could articulate quite distinctly, and seemed to find little difficulty in pronouncing long and hard words after another. He could read nothing except what was written and printed in very large letters, as his vision was so poor. In reading he would still transpose and substitute, and not infrequently omit words. He could converse fairly well, and experienced no difficulty in repeating words and short sentences after another. He could write voluntarily, but transposed, omitted, and added letters, so it was not easy to make much sense out of what he had written. He invariably wrote as he spelled and *vice versa*, but he pronounced the words correctly, no matter what mistakes he had made in writing or spelling, He could copy well, transcribing both printing and writing into script. He evinced no difficulty in thinking in speech. The only defect in speech detected was that observed on testing his writing and spelling. The primary trouble with his speech seemed his inability to spell. He copied quite well and could write correctly if the words were spelled slowly for him. Although considerable time was consumed in making a complete and systematic examination of his speech defect, only those results that showed deviation from the normal are given here.

On April 23, 1896, Dr. W. C. Bane kindly made drawings of his fields. They were as appear below:



R. V., 3/50. Continuous line represents field for white and blue, dotted line that for red.



L. V., 2/50. Continuous line represents field for white and blue, dotted line that for red.

The case reported at considerable length in this paper presents many points of interest. The first operation was performed December 5, 1895. For about two years prior to this date he had shown difficulty in writing, which, on carefully studying, seems to be due to inability to arrange the letters so that they would appear in the regular order in which common usage has assigned them. At the same time he omitted letters and substituted others. It would appear that his speech defect was an inability to spell rather than an inability to write, as he could copy both printing and writing with scarcely a mistake, transcribing both into script. He copied much more rapidly than he could write voluntarily, but he wrote at dictation just as slowly as he wrote voluntarily, except when the words were spelled for him. If a word was spelled for him he wrote it readily and correctly. Further, it should be noted, that he formed his letters well, except when he was suffering severely from headache, or from other causes.

The first operation revealed no pathological condition beyond a cyst in the foot of the second left frontal convolution. He improved rapidly after the immediate effects of this operation had passed away, and his wife wrote me that her husband improved in every way; he seemed brighter, stronger, and happier than he had been for a long time. He tried to do hard work on a ranch which necessitated lifting heavy weights. This proved to be too much for him as his stomach began to trouble him, but no brain symptoms manifested themselves until he injured his head by striking the unprotected brain against the sharp corner of a box. Then all the symptoms of compression of the brain from meningeal hemorrhage became apparent. The mental failure indicated an extensive lesion.

At the second operation which was performed February 13, 1896, the membrane-like substance, by ocular inspection, appeared so well organized, firm and strong that it was thought probable that a more extensive lesion had existed at the time of the first operation than had been detected and removed. Every portion of the material removed at the second operation was preserved and hardened in Müller's fluid for careful microscopical examination. Dr. E. R. Axtell, pathologist to the Hospital, has just completed the examination and reports as follows:

"May 8, 1896.

"The examination of the logwood-stained sections of the membrane, removed from the cranial cavity of W. E. F., reveals nothing but a mass of small, round cells held together by an intercellular substance and by strings of fibrin. In no section do I find any capillaries. The mass presents no capsule, no trabeculæ of connective tissue. Nowhere are there any areas of caseation.

"The pathologic diagnosis is inflammatory lymph."

The above report of the pathologist seems to establish the fact that the morbid condition found at the second operation was recent and probably dated from the receipt of the blow to the brain, thirteen days before. Had it not been for this untoward accident the patient might have made a complete recovery.

Graphic Center.—The motor center for writing has been supposed by some to be located in the foot of the second frontal convolution. In this connection Mills[1] says: "Destruction of this region, which is just in advance of the area for the movements of the fingers, hand, and other parts concerned in writing, it is supposed, would cause a true agraphia, although no clinico-pathological case fully corroberative of this state has been put on record."

As has been observed we may learn to write with a pen or pencil held between the teeth, with the fingers, or with the toes. It is very improbable that the same center would serve to guide the movements of the head, hand, or foot in writing. The function of Broca's center, seems to be to arrange the words for speech utterance. May there not be a cortical center, the function of which is to register the memory of the arrangements of letters for the spelling of words? This is a process that is gradually and laboriously learned, and there must be some portion of the brain in which the memory pictures of the arrangement of letters in the spelling of words are registered. When the loss of ability to write intelligently depends upon the loss of the ability to spell, as shown in the case just reported, in which the patient could copy correctly and write well when the words were spelled for him, the agraphia is secondary and the fault in spelling the primary symptom.

MEDICAL PROGRESS.

The Pathology of Meat-Poisoning.—As the result of an investigation into an epidemic of meat-poisoning due to the use of contaminated ham Van Ermengem (*Centralblatt für Bakteriologie, Parasitenkunde, und Infektionskrankheiten*, B. xix, No. 12, 13, p. 442) has arrived at the conclusion that the view maintained by most authorities that the animals employed in the laboratory for experimental purposes are immune to botulismus is not correct. He has himself succeeded in inducing, with the ham in question, in animals of various species, symptoms resembling those present in persons made ill by the use of the ham as food. Cats proved especially available for experimental purposes, presenting symptoms quite analogous to those observed in cases of botulismus; marked and persistent mydriasis, alteration of the pharyngeal and bronchial secretions, various partial pareses, manifested, among other things, by prolapse of the tongue, aphonia, aphagia, croupy cough, retention of urine, of feces and of bile, etc. Pigeons presented, in addition to paresis of the wings, interesting paralytic phenomena, such as ptosis, inequality of the pupils, etc. Rabbits and guinea-pigs, as well as apes, proved also susceptible, presenting paretic disturbances after poisoning by the mouth. The conclusion is reached that the pathological manifestations induced by the diseased ham were not due to ptomaines, to the toxic alkaloids of putrefaction. The suspected ham displayed none of the subjective or objective manifestations of putrefaction, while putrid meat failed to occasion similar symptoms, which are attributed to a peculiar change in the meat as a result of the fermentative activity of a special micro-organism designated bacillus botulinus. In addi-

[1] "Nervous Diseases by American Authors," p. 436.

tion, the meat was found to contain bacterial poisons. The organism is a large anaerobic bacillus, provided with cilia and capable of movement. It is pathogenic for a number of animals. and induces symptoms like those seen in animals poisoned with the diseased meat or an aqueous maceration. The toxin produced by the bacillus also gives rise to the same symptoms.

Tracheo-esophageal Fistula of Actinomycotic Origin.—In a communication to the Académie de Médicine, PONCET (*Bulletin de la Académie de Médicine*, 1896, No. 15, p. 403) reports the case of a woman, twenty-eight years old, who came under observation with a perforation between the trachea and the esophagus that had existed about two years and a half. The patient, previously free from pathologic manifestations and without tuberculous antecedents, was suddenly seized with paroxysms of violent cough. Several days afterward there supervened a considerable swelling of the neck, without change in the color of the skin, but with serious threatenings of asphyxia. The diagnosis of deep cervical phlegmon was made, which was soon confirmed by the expectoration of a considerable quantity of pus. From this time the respiratory difficulty disappeared, but when the patient attempted to drink she was seized with paroxysms of cough and appearances of imminent suffocation. For six months aliment, and especially liquids, was given through the esophageal sound. The patient learned that she could swallow liquids by inclining the head strongly backward. She was pale and emaciated, and presented no peculiarity other than tenderness upon pressure along the inner border of the left sternomastoid muscle, about one and a half or two inches above the sternum. A diagnosis of tracheo-esophageal fistula was made, and operation successfully undertaken. Examination subsequently of the discharge that took place from the wound revealed the presence of characteristic actinomycotic mycelium, and inquiry of the patient disclosed the fact that she had frequently partaken of uncooked meat. Further, percussion and auscultation elicited signs of probable actinomycotic lesions at the apex of the right lung, without evidences of pleurisy. The patient was accordingly placed upon treatment with iodids and speedily made notable improvement.

THERAPEUTIC NOTES.

Amelioration in a Case of Progressive Myopathy from Thyroid Medication.—LÉPINE (*Lyon Médical*, 1896, No. 19, p. 35) has reported the case of a man, forty-four years old, who had presented symptoms of idiopathic muscular atrophy for eight or nine years, in which improvement in muscular vigor resulted in the sequence of treatment with thyroid gland, though without influence upon the atrophy. The symptom first noted was a difficulty in arising from the ground while the man was engaged in mining. Then general weakness appeared, the scalpula became alar and the left arm commenced to waste. Subsequently the atrophy involved the lumbo-sacral muscles, the serratus magnus, the deltoid and the biceps on the left side, while sensibility remained undisturbed. Other muscles suffered in like manner, but fibrilary contractions were at no time observed and reaction of degeneration could not be elicited. In standing, which was accomplished with difficulty and required support, the abdomen was protruded and the lumbar curve of the spine was increased. After resort to electricity, and other measures usually employed in the treatment of the myopathies, resort was had to the use of thyroid gland. The fresh gland was rubbed up in a mortar, mixed with a little marshmallow-powder, and administered in cachets, each containing 30 grains of gland substance. During the period of two months an average of 900 grains was taken weekly, the amount for the last week being 1800 grains. Under this treatment the patient soon felt better and was able to use his muscular apparatus with greater vigor; and he improved to such a degree that he declined to remain under further observation. No change was observed in the volume of the muscles, and no bad effects were noticed, except occasional palpitation of the heart when the largest dose was being taken. A similar result was secured in a case previously recorded. The influence of suggestion was safely excluded.

Successful Treatment with Thyroid Gland of a Case of Exophthalmic Goiter in Association with Scleroderma.—GRUNFELD (*Wiener medicinische Blätter*, 1896, No. 20, p. 307) has reported the case of a married woman, thirty-three years old, without special hereditary predisposition, in whom, in the sequence of a profound emotional disturbance, symptoms of exophthalmic goiter made their appearance. In the further progress of the case patches of scleroderma developed in various parts of the body. Other measures of treatment having failed, tablets, each of which contained 3¼ grains of thyroid gland from the calf were administered, at first twice, and subsequently thrice daily. In a short time improvement set in, not only in the symptoms of the exophthalmic goiter, but also in those of the scleroderma, and which was maintained even after the withdrawal of the thyroid gland. Other than slight palpitation of the heart no bad symptoms were observed.

Formalin as a Disinfectant.—WALTER has made experiments to determine the bactericidal power of formalin. His conclusions as published in the *Zeitschrift f. Hygiene und Infectionskrankheiten*, vol. xxi, p. 241, 1896, are as follows:

1. A solution of formalin 1–10,000 checks the development of the bacilli of anthrax, cholera, typhoid, diphtheria, and staphylococcus aureus. Very dilute vapors of formalin have the same action.

2. A one per cent. solution of formalin kills pure cultures of pathogenic germs in an hour. This action is still more marked in dilute alcoholic solutions.

3. A three per cent. solution of formalin disinfects the hands perfectly. Further experiments are required to determine any possible injury to the skin from its use.

4. Formalin powders disinfect without injury in twenty-hours cloth and leather goods.

5. A one per cent. solution of formalin is an instant deodorizer of fecal matter. A ten per cent. solution renders such matter sterile in ten minutes.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, AUGUST 1, 1896.

THE INSULT TO THE PROFESSION.

SOME of our contemporaries who have attempted to follow, as presented in the columns of the NEWS, the position in which the recent events in connection with Bellevue Hospital have placed the profession, are still somewhat in the dark in regard to the exact condition of affairs. The position that the NEWS has taken is to resent the affront that was placed upon the profession and to resist the harmful influence upon the public of the Commissioner's rash and unwise action. The infringement upon the rights of the Medical Board of Bellevue Hospital was properly resented by that Board, and an effort was made to induce the Commissioners to see the mistake that they were making.

At first certain cases were designated in the alcoholic wards as special patients of Dr. Oppenheimer. The visiting physician then on duty expostulated with the Commissioners and notified them that the innovation was demoralizing his service, and asked that if the test of this cure was to be made in the wards of Bellevue Hospital the formula of its composition be placed in his hands and that the experiment be conducted by the regular visiting physicians of the Hospital. The proposition to reveal the composition of the "cure" seemed so preposterous to its proprietor that it was indignantly refused; but in order to allow him to continue his experimentation within the Hospital without friction with the Visiting Board, the specified cases were taken out of the alcoholic ward and all the beds in Ward 33 were set aside for the specific use of the proprietor of the "cure."

When a report reached the Commissioners that two deaths had occurred in Ward 33, they at once addressed a communication to the Medical Board, asking them to investigate the conduct of the experiment and report to them as to the benefits of the treatment, saying: "We are chiefly interested as to whether, as inferred, as public officers we have been instrumental in the death of one and placing in jeopardy the lives of several other patients by permitting the treatment." In reply to this the Medical Board submitted the following:

NEW YORK, July 1st.

To the Honorable Board of Commissioners:

In answer to the communication of June 27th from your Honorable Board to the Medical Board of Bellevue Hospital, we respectfully submit the following:

* * * * * *

In regard to the specific matter referred to in your communication, while we are always ready to investigate any scientific problem presented to us, we are unable to find any logical basis for the investigation of the action of any remedy or remedies, or the efficacy of any method of treatment which does not involve a full knowledge of the composition of the remedy, together with accurate and full details of the proposed plan of treatment; we consequently have and can have no report to make of the specific cases referred to in your communication.

In view of our long public service in your hospitals, we feel justified in deprecating the trial in the hospital of any secret remedy or plan of treatment as opposed to the universally recognized traditions of our profession, and to the best interests of the public and the sick poor under our care.

Signed by the Secretary and President of the Medical Board.

This terminated the communications between the Medical Board and Commissioners in regard to the use of the Hospital.

The Medical Board, however, can take care of itself. With that we have no concern. But the principle involved in this action of the Commissioners is far more important than the administration of any one hospital or any number of hospitals. It strikes at the fundamental doctrine of our profession, namely, that all discoveries of remedies that are beneficial to the human race, when made by one of our number, should be the common property of the whole profession, and should be disseminated as widely as possible throughout the world, and administered by those who make it their life-work to relieve the ailments of mankind.

The mercenary motives underlying the exploitation of this "cure," as exposed in the previous issue of the MEDICAL NEWS, wherein we gave a copy of the charter of the company and the affidavit of its president, that the stock had been fully paid for, must be clear to any sane mind. The fact that the "cure" takes its position simply as one of many others that have been exploited and are being exploited at the present time, is also apparent. It must, therefore, be clear to the Commissioners of Charities, that instead of conferring a boon upon humanity by this wide advertisement of a secret nostrum, they are doing one of the greatest wrongs that it is possible for them to commit. In view of all these facts, we call upon the Commissioners to put a stop at once to the further continuance of this fiasco. They have made the great mistake of their term of office. The mistake has been made clear to them, and the wise action for them now is to correct it as soon as possible.

CAMPAIGN OF THE BOARD OF HEALTH AGAINST FILTH AND DEGRADATION.

THE action taken last week by the Health Department of New York City, in the matter of certain tenements, is gratifying and encouraging to everyone who sincerely desires the limitation of disease and the amelioration of the condition of the poor. Radical, and perhaps severe, it is the only remedy for the evil. The uncompromising policy of this Department in demanding, some years ago, the introduction of water into some filthy and unsanitary tenements belonging to Trinity Church corporation was met by legal action, but the courts sustained the Board of Health. In the present instance, the courts will probably pursue a similar course if litigation should result from this unprecedented action of the Board.

Forty-two rear tenements have been condemned by the Board, and ordered to be vacated and razed to the ground. Most of these houses are situated in Cherry, Mulberry, Thompson, and Greenwich streets and in West Broadway. Altogether they afford accommodations for about 1700 persons. During the past five years the average death-rate has been as high as seventy-five per thousand in one of the Mulberry street rookeries, while in the whole city the average annual death-rate is only twenty-two per thousand. In one double house in Cherry street 472 people were crowded together without air or sunlight. In many instances but six feet of space intervened between the front and rear buildings, and in several houses direct sunlight had no access to any of the rooms.

It is surprising that human beings will consent to occupy such nests of filth and breathe such a defiled atmosphere as did the disease-threatened tenants of the condemned structures; but it is an established fact that certain people prefer such quarters, and that these people are at once the prey and the distributors of many infectious diseases and the foster-parents of much criminality. No one should be allowed to live in such reeking holes, for mental and moral debasement must result, with a swift corollary of crime. The Health Department is convinced that sunlight, together with soap and water, will accomplish for these wretched beings what no other agency can accomplish.

It gives us pleasure to learn that the Board contemplates the condemnation of a hundred similar houses, now under investigation. The influence of every member of the profession should be enlisted on the side of the Health Department, should occasion arise for sustaining its course.

SOME LITTLE-RECOGNIZED FORMS OF LITHEMIA OR "LATENT GOUT."

TEN or fifteen years ago nothing was commoner than to read or hear the statement in professional works and gatherings, "We have very little gout in any form in America," and many

were the theories advanced to account for our comparative immunity and the special liability of our English cousins, in most of which "the wine when it is red" was, as usual, the chief scapegoat, and our "simpler and more temperate habits" our safeguard, the thesis usually ending either with a smug little moral tag and tribute to Miss Willard or a reference to "luxurious and effete despotisms." So widespread and firmly rooted was this connection in the popular mind that in some Western prohibition communities a statement to a patient that he had gouty trouble was resented as an aspersion upon his moral character, and not unfrequently cost the doctor his case. However, we know better now, and are rapidly coming to doubt both the fact and its explanation, as several of our best authorities assert, that alcohol has very little to do with the causation of gout, while we are recognizing on every hand a multitude of morbid conditions, which are of gouty or lithemic origin. But, first of all, a few words as to the terms which we are using.

We regard "gout" and "lithemia" as practically synonymous terms, the latter simply being the wider of the two, and including both the "frank" and the "latent" gout of the older authors. We prefer to use the latter in discussing these subjects simply for this reason, and because gout has become so firmly associated with a red and swollen great-toe, that its application to milder or less obvious forms of the diathesis is apt to cause confusion. Next we must frankly admit that the term "lithemia" is not a chemical, but a clinical one, and stands for the presence of those substances or changes in the blood-plasma which are accompanied by uric acid and the urates. The latter substances are responsible probably for only a part of the disturbances due to this hemic state, but are the only factors readily recognizable and calculable, and hence serve as a convenient index and criterion of the whole group; something after the manner of the CO_2 of vitiated air, of the sulphureted hydrogen of sewer-gas, or of the urea of uremia, although, of course, much more actively concerned than any of these substances.

As to the essential nature of this condition, we shall simply improve upon the suggestion of Garrod and define it briefly as a reversion or falling back on the part of the cells of the liver primarily, and of the skeletal muscles secondarily, to a lower stage of metabolic activity (avian or reptilian), resulting in the production of uric acids, its salts, and other extractives associated therewith, in place of the urea group. As to its causes, they are legion; *any* influence which lowers the vital tone of the organism, as a whole, may provoke it. Nor is its occurrence by any means confined to the human species. Our first cousin —dietetically—the pig, not infrequently suffers from the deposit of tophi, while various birds, especially parrots, develop similar deposits. The interesting thing about bird-tophi is that they consist of the metabolic product of a still lower ancestral stage, guanin, which is the normal urinary excretion of fish and mollusks.

A process which has such deep and widespread roots as this in our past history might naturally be expected to be wellnigh universal, and such is actually the case. Instead of lithemia being rare in America, we venture the assertion that it is by far the most frequent, single pathologic alteration which we meet with in our practice.

Sydenham's witty dictum that gout is the "*morbus dominorum et dominus morborum*" is as true to-day and here, as in England in his time. 'Tis true, it doesn't often advertise itself by attacking the great toe, but milder forms of the very same process are simply innumerable. It appears under as many titles as a Chicago divorcée. For instance, a large proportion of the cases of our "national disease," dyspepsia, are not true disease of the stomach at all, but simply gastric manifestations of the lithemic state and will completely disappear when this latter condition is removed. A large majority of our neuralgias, headaches, and migraines own the same parentage. About all that we really know of rheumatism is that, outside of the acute articular variety, two-thirds of it is gout. The muscular variety is a beautiful case in point. The term makes a beautifully neat, soothing, and satisfying diagnosis, but reminds one of Agassiz's student's definition of the crab as "a small, red fish, which walks backward," which, as the professor commented, was an excellent definition, but slightly defective in

one or two particulars, inasmuch as a crab is not a fish, does not walk backward, and is not red until after it is boiled. Whatever else muscular rheumatism may be, it certainly is not rheumatism, nor has it anything to do directly with the muscle-cells. It is surprising how many cases of chronic diarrhea, even of the "army" variety, in members of the G. A. R., will yield to anti-lithemic treatment, while as to irritable bladder, Carlsbad lithia waters and a suitable diet will be found almost a specific in many cases, not only in men of all ages, but even in young and nervous women supposed to be suffering from "displacements." Any laryngologist of experience will tell you how often in his patients he recognizes the "purple throat," a deep garnet-red pharynx, with a bluish tinge about the palate and fauces, which is the local manifestation of uric-acidemia, and how often even chronic laryngitis is relieved by a thorough "flushing" and small doses of the iodids.

In eczema, the skin specialist regards diet and the correction of any disturbances of renal metabolism as second only to the removal of all local irritation; while "eczema of the capillaries," as Stockton has well called the "interstitial" form of that dread process, Bright's disease, appears to be almost inseparably connected with precedent lithemia as locomotor ataxia is with syphilis. We are well aware that these are sweeping claims and that the domain of this "Pandora's box" shades by such insensible gradations with that of the purely and directly intestinal toxemias that it is hard to decide which is the chief or causal factor in many of these cases. Yet it is our deliberate conviction that this "reversionary" process is one of the commonest disturbances which occur in our tissues, as, indeed, was to have been expected on evolutionary grounds, inasmuch as there could be nothing easier for our muscle- and liver-cells than to fall back one ancestral stage in their metabolism.

The general line of treatment adopted bears out this view. If it could be compressed into one sentence, it would be the old classic prescription to "live on a shilling a day and earn it." Exercise and sunshine come first of all. Keep up all our tissues to the full mammalian standard of metabolism. Then the next great vital necessity, water, and lots of it, in the form of Carlsbad or Friedrichshall, at first for an alimentary flush, and of lithia or strontia waters for a renal one later, if your taste prefer, but the H_2O is the chief thing. Let the diet be as nearly of the "field-hand" variety as the appetite will take, *plenty* of meat, fresh vegetables, and sour fruits, and very little starch or sugars. Sour wines, especially claret, bitter beer, and whiskey up to the "food" limit, if your patient is anemic; it is the fermentable sugars in port, madeira, and ordinary beers that do the mischief, and *not* the alcohol. A spoonful of strawberry jam or a slice of gooseberry tart will provoke an outbreak in a gouty subject as promptly and surely as a glass of port wine.

As for tonics, anything that will whip the cells up to the mammalian level is in order; musk, arsenic, strychnia, and, chief of all, that grand old crystallized sea-breeze, which carries our cells back like the echo of a forgotten song to the days of their sturdy, happy marine childhood on the salt sea beach—potassium iodid.

WOODS HUTCHINSON, M.D.

ECHOES AND NEWS.

Secondary Diphtheritic Tests in the Public Schools of Paris.—The Prefect of the Seine has recently addressed a circular to medical inspectors of schools, calling upon them to supply in addition to the usual certificate of recovery of scholars from diphtheria, another issued by the Bacteriological Service of the City of Paris, affirming the absence of Loeffler's bacillus from the mouths and throats of those same children previous to their readmission to school.

Election in the Royal College of Surgeons, England.—On July 9th the Royal College of Surgeons elected for president, Sir William MacCormac, and for vice-presidents, Mr. Charles N. Macnamara and Mr. John Langton. These are all surgeons of distinguished ability, and their choice must give general satisfaction. It is a source of much pleasure to the many friends and admirers Sir William acquired during his visit to America to note that such honor has been so worthily conferred.

A Graduate but not a Doctor.—The Edinburgh College of Physicians, following the example of her Irish neighbor, has appended to her laws the following: "The diploma granted by the College shall not entitle the holder, by virtue of such diploma, to assume the title of Doctor, or to append to his name the title of Doctor of Medicine,

or the letters M.D., or other abbreviation which might suggest that the holder had obtained the degree of Doctor of Medicine from the University."

Cholera Among the English Troops in the Soudan.—The death of Major Owen, from cholera, while in command of the Arab scouts, together with a limited number of cases of the same disease among the English soldiers, makes a picture with no reassuring features for the expedition. At least seven hundred cases have occurred in the Nile valley, outside Alexandria and Cairo. There are grounds for fear of a possible disaster which may prove worse than defeat.

Not Responsible for an Error of Judgment,—It has been recently decided by the English Court of Appeals that a physician cannot be held responsible for an error of judgment, provided he can show that reasonable competency and care has been brought to the case. The case in question was one in which Dr. Russell had been called to examine a lady, against whom suit for divorce was afterward brought, upon his report of her marital incompetency. She denied the existence of such cause, and brought an action against him for damages, in which the above-mentioned decision was given.

A Bullet in the Brain Located by the X-Rays.—MM. Brissaud and Loude presented to the Académie des Sciences of Paris a skiagraph of the head of a man who presented a variety of most interesting neurological symptoms resulting from a bullet which he carried in his brain. Although not clearly defined, owing in part to involuntary movements during the exposure, the missile was clearly distinguished in the exact location in which both the nervous manifestations and surgical evidences had placed it. If we are not mistaken, this is the first time a bullet has been pictured in the living human brain.

Changes in the Faculty.—At a meeting of the faculty of the Kentucky School of Medicine of Louisville, Ky., held on the 21st day of July, by a vote of five to one, the chairs occupied by Dr. W. H. Wathen and Dr. M. F. Coomes were declared vacant. It has been an open secret among the profession for a number of years that there has been friction among the faculty of this school, and some credence was given this when about a year ago it became known that Dr. Wathen had been deposed from the position of dean of the faculty, which he had occupied for a number of years, and that Dr. S. E. Woody had been elected in in his place.

The Tubercle Bacillus and the X-Rays.—M. Lortel has given the results of his efforts to determine the influence of the X-rays upon tuberculosis. He injected eight guinea-pigs with a culture taken from another pig. Three of these, after three days, were daily subjected to the influence of the Crookes' tube upon the point of injection for one hour over a period of fifty-four days. At the end of forty-five days the other five animals showed suppurating abscesses about the place of injection, while the three remained healthy and increased in weight. This is interesting, as no other experimenter (outside of Chicago) has found any appreciable effect exerted by these rays upon the life or growth of germ life.

Hospital Infection by Tuberculosis.—Dr. Paul P. Prendergast, who died in Brooklyn, on July 10th, must be regarded as the victim of a hospital infection by tuberculosis. This young physician was graduated, in 1894, from the College of Physicians and Surgeons. Until about one year ago, he had been in good health; he was fully six feet in height, and weighed two hundred pounds. After graduation, he attended most assiduously to his duties at the hospitals, at the Sloane Maternity in New York, and at the St. Mary's and Seney Hospitals in Brooklyn. He sought relief in the Adirondacks and California, but his efforts to recover were unfortunately fruitless.

The Kind of Medical Men to Avoid.—The one who has acute exacerbations of insanity when exposed to any new fad; the one who is always successful with all his difficult operations; the one who always sees hundreds of cases of a rare disease; the one who can always match your case and improve on your treatment; the one who always finds you have omitted something in the examination of your case; the one who thinks he can talk well and is always ready to discuss any paper of the evening; the one who is always first to do the new operation; the one who is in a chronic fear of his being anticipated in his important discoveries; the one who, in consultation, feels it is his conscientious duty to explain to the patient why he differs from the attending physician.—*Canada Lancet.*

Diphtheria Antitoxin in Great Britain.—Appreciating the apparent fact that in the British Isles the serum treatment of diphtheria had not attained the results reported from the Continent, *The Lancet* conceived the idea that it was due possibly to a difference in the antitoxin, and to decide the question caused a long and careful investigation to be made which abundantly substantiates the suspicion. It was thus shown that few, if any, of the English preparations were reliable in strength, in which particular wide variations were discovered. Great credit is due *The Lancet* for the good work thus accomplished. We append the conclusions drawn from this report: "(1) That a common standard of estimating the strength of antitoxin serum should be agreed upon by the English manufacturers. (2) That no serum should ever be sent out containing less than sixty normal antitoxin units per c.c. (3) That antitoxin serum of higher strengths must also be provided to meet the requirements of treatment in more severe cases of diphtheria. (4) That every sample of antitoxin serum sold should be plainly marked with the antitoxic strength of the serum (number of normal antitoxin units per c.c.), the quantity of serum present in the bottle, and the date of issue."

Obituary.—Dr. Edward Gutmann, who died in this city on July 21st, was born at Halle, Germany, in 1828, and was educated at the University of Berlin. He came to this country in 1854 and practised medicine in this city until 1869, when he gave up his practice to travel abroad. The next few years of his life, Dr. Gutmann devoted to the study of ancient and medieval art, and in his search

for rare pictures, books, and statuary, he visited Europe, Asia, and Africa, where he made a special study of Egyptian art. Dr. Gutmann spent several years in Rome, where he gathered a collection of books of art, particularly those of the Renaissance period. On his return to this city he published a treatise on "The Sarcophagus and the Grave Monuments of Old Greece and Rome." This book was issued by subscription, and among the subscribers were Queen Victoria, King Humbert of Italy, Emperor William of Germany, and many other distinguished persons throughout Europe. The only copies sold in this country were to the Smithsonian Institution and to Johns Hopkins University. Dr. Gutmann was a member of the Natural History Museum, the Metropolitan Art Museum, and the Freundschaft Club, and has probably bequeathed his splendid library of over six thousand volumes and his art collection to the New York Metropolitan Museum of Art.

The Hazards of the Medical Life Commercially Recognized.—According to the *Insurance Herald*, certain insurance companies are about to assume different relations toward medical men as "risks." The conviction is gradually forcing itself upon managers of accident insurance companies that physicians are extra-hazardous risks, and do not belong in the preferred class, where they are at present generally listed. A comparison between the probable hazards incurred by a doctor and a member of any other profession or business classed as preferred, illustrates this point at a glance. Possibly the most objectionable feature about the physician's hazard is that many injuries which are slight and of no consequence to other people, are total disabilities to doctors, and consequently causes for indemnity claims. For instance, a doctor performing a surgical operation, injures his finger or hand. While the injury may be in itself slight, it is very likely to be such as to prevent the doctor from resuming his occupation until the wound is entirely healed, and during the interval the company is required to pay indemnity. Then there is the "horse hazard." A horse and buggy is a necessity to every doctor with any practice at all, and he is thus subject to runaway and collision accidents to an unusual degree, owing to the incessant use of the horse, and the rapid pace at which a doctor is usually obliged to drive.

Reform in New York Charities that Receive Over $20,000,000.—Dr. Stephen Smith and Dr. E. V. Stoddard, are members of a newly appointed committee of inspection of charities, under the New York State Board of Charities. Their duties relate largely to the economic expenditure of moneys, bestowed by the State upon hospitals, dispensaries, and other charitable institutions. Under the new State constitution, supplemented by laws passed last winter, it is provided that the State board of charities "shall visit, inspect, and maintain a general supervision of all institutions, societies, or associations which are of charitable, eleemosynary, correctional, or reformatory character, whether State or municipal, incorporated or not incorporated, which are made subject to its supervision by the constitution or by law." The committee of inspection will investigate all charities in Brooklyn and New York, both public and private, and will organize a system of direct supervision over all charitable work. The State has appropriated $10,000 for this year's work. The charitable donations last year in New York State, public and private, amounted to the immense sum of $23,000,000. No other State spends nearly as much. It is to provide for the wisest distribution of this money that the present supervision has been provided.

SOCIETY PROCEEDINGS.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Monday, May 18, 1896.

The president, JOSEPH E. JANVRIN, M.D., in the chair.

LOUIS F. BISHOP, M.D., of New York City, presented a case of

PRIMARY PLUGGING OF THE BRACHIAL ARTERY

in a girl fifteen years of age. The trouble had come on quite suddenly, and was characterized by a total loss of tactile sensibility in the hand on the affected side. There was no radial pulse, and no arterial pulsation up to the upper third of the arm, where a cord-like hardness could be felt. There was unquestionably a neuritis of the arm, due to some traumatism, and one result produced was a dry gangrene of two of the finger-tips and of the thumb. He had arrived at the conclusion that this was a case of primary plugging of brachial artery. At the present time collateral circulation seemed being gradually established, and there was a slow amelioration of the symptoms. There was apparently no cardiac disease, and the patient was not suffering from diabetes.

CHARLES J. PROBEN, M.D., of New York, read a paper on

EXPERIENCE WITH PILOCARPIN IN THE TREATMENT OF UREMIA OF BRIGHT'S DISEASE.

In the condition named, the desirability of temporarily acting on the skin had long been recognized, and when jaborandi, and its active principle, pilocarpin, were brought to the attention of the profession, it was hoped that a very useful addition to our therapeutical armamentarium had been gained. It was soon found, however, that the dangers attending the use of this agent, militated very seriously against its general employment. Having described the physiological affects of pilocarpin, he stated that the depression of the heart's action produced by it was very similar to that caused by nicotin. It had been found that the toxic effects of the drug were best overcome by atropin, and the antagonism between the two agents was now well established. In cases of atropin poisoning, he thought pilocarpin should be more frequently used than was now the case, although the fact could not be denied that atropia was more efficient in pilocarpin poisoning than pilocarpin was in atropia poisoning. Where toxic effects resulted from the administration of pilocarpin, the ordinary circulatory stimulants should also be resorted to.

Dr. Proben then referred to a number of authorities,

among them Fordyce Barker, who had favored the use of pilocarpin, and who then had fatal cases in patients suffering from puerperal uremia, Henrop, Singer, Loomis, and Strümpel. Many fatal cases were also recorded in general medical literature. The question then arose, were we justified in continuing the use of this agent? There was still a division of opinion on this subject, and Osler, who after giving it up entirely, had more recently returned to its cautious employment, in doses of from one-eighth to one-sixth of a grain. Dr. Proben expressed the opinion that probably the only cases in which pilocarpin could be used with safety were those in which there was simple hypertrophy of the heart, with a strong action. The contractive power of the heart was what we had to depend upon as a guide for its administration. Its employment was certainly contraindicated if there were present any dulness over the lungs, or pneumonia, emphysema, pleurisy, coma, fatty degeneration of the heart, or cardiac insufficiency. To ascertain the condition of the cardiac muscle, auscultation with the binaural stethoscope was called for, and any impairment of the first sound of the heart should make one hesitate to use pilocarpin.

At this point he said that he would digress for a moment to express his conviction that in the intravenous injection of hot saline solutions, as advocated by Dr. Beverly Robinson and others, we had an agent which was far more efficient, as well as safer, than pilocarpin in bringing about the relief sought for in anemic cases. He had now used this in two cases, and he believed it was in every way preferable to pilocarpin.

He then proceeded to give the details of three cases in his experience in which pilocarpin had produced fatal results. The first was that of a female, forty-two years of age, suffering from chronic uremia. The heart and lungs were apparently normal. One-tenth of a grain of pilocarpin hydrochlorate was injected subcutaneously. Collapse from cardiac paralysis resulted and death ensued in the course of an hour, notwithstanding the most active efforts to avert the catastrophe. In the second case, one of chronic interstitial nephritis, death from collapse from cardiac paralysis resulted within three hours after the hypodermic use of pilocarpin. In the third case, in which the patient was also suffering from cirrhosis of the liver, fatal collapse likewise resulted. In this instance one-fifth of a grain of pilocarpin was injected. In none of these cases were there any contraindications to its use, and yet a rapidly fatal result followed in all of them. On the whole, therefore, while he believed that in some cases pilocarpin could undoubtedly be given with benefit, he thought that, on account of its marked depressant effect upon the heart's action, its administration should be banished from the treatment of Bright's disease.

Dr. Proben then went on to say that within the past week, after his paper had been finished, he had met with a case of puerperal eclampsia. Labor came on about two weeks before the expected time. He was called to the patient after one convulsion had occurred. He summoned assistance, administered chloroform, and proceeded to deliver with forceps, although the os uteri was not yet fully dilated. After delivery there was another convulsion. The urine was found to contain about twenty per cent. of albumin. The patient seemed to be doing well, and he finally left her. In the middle of the night, however, he was hastily called, and found that she had had another convulsion and that she had scarcely passed any urine at all. He at once opened the median cephalic vein, and injected two quarts of a hot saline solution. The effect was most happy. Within two hours she passed a considerable quantity of urine, and she had no more convulsions. During the twenty-four hours following the saline injection she passed no less than 109 ounces of urine, while in the preceding twenty-four hours she had passed only 2 ounces. His experience in this case had confirmed him in the conviction that we had in this procedure a resource more reliable than any drug.

DISCUSSION.

J. Lewis Smith, M.D., of New York, said that though he had had no experience with pilocarpin in adult life, he had records of a number of cases of scarlatinal nephritis in children, in which he had employed it. Notwithstanding the fatal results noted by the reader of the paper and others, he believed that it was in reality a very useful remedy, and that in time it would come to be given in such a way that it would be generally recognized as such. Some time ago he remembered a well-known practitioner remarking to him that he would never use pilocarpin again. The reason that he gave for this was that he had found that it was liable to produce a kind of bronchorrhea, which was almost always fatal. Not long after he heard this remark, Dr. Smith was called in consultation to see a child, two years of age, who had recently had scarlet fever. The attack was not a severe one, but it was followed by kidney disease, which resulted in general anasarca. A single dose of pilocarpin was administered, and as a result of this bronchorrhea was rapidly produced, accompanied by the most intense dyspnea, so that the patient soon succumbed.

On the other hand, he had seen other cases in which the remedy acted with the most happy effect. It was, therefore, a sword with two edges, and he hoped that a way would be discovered by which it could be administered in comparative safety. Perhaps if it were given in connection with some such heart stimulant as strychnia, in large doses, its dangerous effects might be, to a great extent, obviated. Dr. Smith then proceeded to give the details of two or three cases in which great benefit was derived from the use of pilocarpin. One of them was as follows: A child, five years old, who had had a severe attack of scarlatina, and was apparently convalescing admirably, when general anasarca rapidly set in. The attempt was made to administer infusion of digitalis and acetate of potassium, but this was for the most part vomited, as the stomach was exceedingly irritable. Only two ounces of urine passed in twenty-four hours, and uremic convulsions ensued. The pulse was quick and full, and the axillary temperature 103. The convulsions, after lasting an hour, were controlled by potassium bromid and chloral. One thirty-second of a grain of muriate of pilocarpin was then ordered every three hours. This remedy was not vomited,

and it had the effect of causing free diaphoresis and an increase in the quantity of urine passed. Afterward the child had eclampsia occasionally, but the convulsions were readily controlled by chloral hydrate administered by the rectum. She did not vomit again, and gradually recovered under the use of pilocarpin, which was afterward given at six instead of three hour intervals.

Other simllar cases were referred to, and Dr. Smith said that in these instances the patients under ordinary methods of treatment would probably have died. The only fatal case which he had seen in a child was one he had met with in consultation, where death seemed to be due to bronchorrhea. In general, he thought the danger in the use of pilocarpin was probably more from the accumulation of serum and mucus in the chest than from the depressing effect of the drug upon the heart.

J. BLAKE WHITE, M.D., of New York, said that his experience was a little different from that of either Dr. Proben or Dr. Smith. While he believed that pilocarpin was a dangerous remedy, which should always be used with great discrimination, personally he had never seen any bad effects from it. His own observation was perhaps more limited than that of Dr. Proben, but he had employed the remedy in rather a different way. It had been his practice to give only from one-twelfth to one-sixth of a grain, always hypodermically, and he had usually combined with it some cardiac stimulant, such as strychnia or digitalis. It seemed to him that in the cases of Barker and Singer, referred to in the paper, the cerebral and pulmonary edema noted was not necessarily due to the drug, but might perhaps have resulted from the disease itself, as Rees had pointed out, that such effusions sometimes occurred in uremia. In Dr. Proben's own cases the patients appeared to be enfeebled, and hence not able to resist the depressing effects of the remedy. It was a singular thing that children were specifically tolerant of pilocarpin, and that it was probable that it could be more safely given to them in proportionally larger doses than was the case in adults.

He believed the remedy to be a very valuable one, but on account of the danger connected with its use, as he had said before, it should always be employed with great discrimination. In order to produce the best effects of the drug he had always found it necessary to assist diaphoresis by wrapping the patient in a blanket. Another point of importance was, that after the diaphoresis had been established it should not be allowed to subside too suddenly, but that the recurrence to normal should be accomplished gradually.

DR. PROBEN, in closing the discussion, said that the tolerance for pilocarpin in children was now pretty well established, and that, as a rule, they bore the remedy much better than adults. As to the so-called case of bronchorrhea, referred to by Dr. Smith, he believed that the condition was probably simple edema of the lungs, due to cardiac paralysis. In cases where pilocarpin produced toxic effects the serum was exuded into the parenchyma of the lungs, and not simply into the bronchi. He thought the administration of stimulants, such as alcohol and strychnia, in connection with pilocarpin, a good idea. Atropia was the best antagonist of the drug, but unfortunately it could not be used on account of its action in suppressing diaphoresis. As to Barker and Singer's cases, he thought that it must be admitted that the rapidly fatal results were really due to the pilocarpin, as modern authors did not endorse the old idea that edema of the brain was a natural result of the disease. As in the cases, in which pilocarpin was indicated, it was of the utmost importance that rapid results should be accomplished. He believed that the drug should always be administered hypodermically.

WM. M. LESZYNSKY, M.D., of New York, read a paper upon

THE DIAGNOSIS AND TREATMENT OF PARALYSIS OF PERIPHERAL ORIGIN.

He said that his special object in preparing this paper was to emphasize the great practical value of electricity in the matter of diagnosis. It was based on nearly four hundred cases, many of which had been under observation for a number of months. The field was such a large one that he proposed to confine his remarks to facial paralysis and paralysis of the upper extremities. Given a case of paralysis, it was very important to determine as speedily as possible whether it depended on a lesion of the brain, a lesion of the spinal cord, or was of peripheral origin.

The most common cause of peripheral paralyses was traumatism, either from direct wounding of the nerve, from pressure during sleep, or from refrigeration. Paralysis affecting the face, but not involving any other parts, was rarely of cerebral origin. When facial paralysis was due to a lesion of the brain it affected lower branches of the nerve merely while facial paralysis of peripheral origin affected all the branches. In peripheral facial paralysis the faradic irritability of the muscles was either impaired or entirely lost within ten days. The ordinary galvanic formula was also reversed, the anodal closing contraction being greater than the cathodal. Under these circumstances we had what is known as the reaction of degeneration. The application of electricity thus enables us to make a differential diagnosis. The reactions noted indicated some lesion either of the nucleus or in the course of the nerve trunk.

In the treatment the galvanic current should be used. In almost all cases, however, a greater or less improvement gradually resulted, no difference what treatment was employed. In some cases of fascial paralysis there was an exposure of the eyeball, and it was highly important that measures should be taken to protect the latter from injury when this was the case. Otherwise, ulceration or perforation of the cornea might result.

In peripheral paralysis of the upper extremity, the brachial plexus might be affected in a number of its branches, or sometimes only in one. A case was related in a male of thirty-eight, in which all the groups of muscles of the arm and shoulder were profoundly affected except the biceps group, which was only slightly implicated. Almost complete recovery took place in two years. The paralysis met with in infants as a result of pressure during parturition was sometimes mistaken for disease of meningeal origin. In a few weeks, however, by means

of electricity, a differential diagnosis could be made. Paralysis of the musculo-spiral nerve, producing wrist-drop, was usually produced by pressure, and was common after profound alcoholic stupor. It might be mistaken for lead paralysis, but in the latter one side was usually affected before the other.

Peripheral paralyses could, for convenience, be divided into three classes, *first*, slight, *second*, medium, and *third*, severe. The slight form would recover, without treatment, in about fourteen days. In the medium form, with partial reaction of degeneration, two months were required; and in the severe form, with more or less complete reaction of degeneration, nine months. The question naturally arose, has electricity really a beneficial effect in these cases? Dr. Leszynsky said that, judging from a pretty large experience, he felt confident that the process of regeneration is materially expedited by the judicious use of electricity. Discrimination, however, should be used in its employment, and care should be taken that the muscles should not be over-stimulated by too strong a galvanic current. The electrical treatment should be commenced within two or three weeks after the occurrence of the paralysis, unless severe neuritis were present. He did not think *suggestion* of much value in this class of cases, and certainly it was of no use in young children. In traumatic division of a severe operation, procedures should at once be taken. In addition to electricity, massage and other appropriate measures should be employed, and in certain instances mechanical appliances were called for.

The paper was discussed by Drs. H. W. Berg, L. F. Bishop, and J. Blake White, and the discussion was closed by Dr. Leszynsky.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, May 13, 1896.

The President, Dr. James C. Wilson, in the chair.

Silas Updegrove, M.D., of Philadelphia, read a paper entitled

NECESSITY FOR THE STATE TO DEMAND THE ADOPTION BY THE COLLEGES OF A MORE UNIFORM STANDARD OF EDUCATIONAL REQUIREMENT FOR THE DEGREE OF DOCTOR OF MEDICINE.

It was stated that a recent application to the Assembly of the State in regard to the matter had resulted in the establishment of three boards instead of one for the examination of candidates for a license to practise medicine. To justify the creation of more than one board it was claimed that each was to represent a certain school or method of cure. All diseases, the speaker remarked, might be divided into two classes, viz., the curable and the incurable. Diphtheria was an example of the curable class. Cases of diphtheria get well under treatment, or even without treatment. Other do not get well under any circumstances. No formula is known that can be adopted as a method of cure for all cases of diphtheria or other disease of the class to which it belongs, and no reputable college should adopt a formula of cure as the basis of educational requirement for the degree of doctor of medicine. The speaker compared the requirement of a knowledge and acceptance of the law of similars by medical colleges with that of an acceptance and knowledge of the Ptolemaic system of astronomy by other institutions as a condition of a degree. Dr. Updegrove declared that in order that there be true medical education there must be some recognized authority by the State upon medical questions. This was so, he said, in other departments. In law, the Supreme court is the authority; in astronomy, those learned in astronomy; then, why should not the medical profession of the world be accepted as authority in declaring that a universal method of cure has not been established? Dr. Updegrove said that a world of trouble might have been saved a half century ago if the medical profession had been recognized as an authority in declaring against the law of similars. He also referred to the absurdity of submitting legal questions to the decision of the public instead of to a legal tribunal; but, he added, medical questions were passed upon and decided by those who had no knowledge of medicine. To further emphasize the absurdity the speaker gave some decisions of the Supreme Court regarding disputed questions. One case was in regard to calling a homeopath a quack. The court assumed that the homeopath had a system, and did not assume that this system had a basis of false pretense, and a fine of one hundred dollars was imposed upon the defendant. Another suit was for malpractice. The court ruled that if there are distinct schools of practice, and a physician of one of the schools is called in, his treatment is to be tested by the general doctrine of his school. In one case, tried in the State of Iowa, the court ruled that a physician is expected to practise according to his professed and avowed system. The court further said that there is no particular system of medicine established or favored by the laws of Iowa, and as no system is upheld, none is prohibited. The regular system is still regarded by the law with no partiality or distinguished favor, nor is it recognized as the exclusive standard or test by which other systems are to be judged.

J. Solis-Cohen, M.D., of Philadelphia, exhibited a

TONGUE DEPRESSOR

by means of which the interior of the larynx and treachea can be inspected directly without the aid of a laryngoscopic mirror. The instrument was a device of Dr. Kirstein of Berlin, who called it an autoscope, but the term is unfortunate, the word meaning examination of oneself. A better name for the instrument would be ortholaryngoscope. In reality, the device was a tongue depressor. The difficulty in making a direct examination of the larynx is due to the presence of the epiglottis. To overcome this the laryngoscopic mirror has been deviced. The ortholaryngoscope is so constructed as to get the epiglottis out of the way of direct inspection. This instrument is practically a univalve speculum of sufficient length to reach the base of the tongue in front of the epiglottis. This organ is connected with the tongue by the glosso-epiglottic ligaments. When these ligaments are pressed downward and forward toward the hyoid bone, the epiglottis is tilted forward and the dorsum of the tongue and the larynx are brought into the same place. During the

examination the patient if seated, with neck extended and the head thrown back, and with good illumination, the examiner can look directly into the larynx. In certain cases in which the epiglottis cannot be pulled forward in the way described, a straight instrument is used, which is brought over the cocainized epiglottis, which is thus brought forward. An attachment can slide over the tongue depressor for the purpose of avoiding trouble with the teeth and moustache. As the patient naturally is apt to close the mouth, a cap is placed upon the instrument. The advantage of this tongue depressor is, that instead of the ordinary laryngoscopic instruments, direct instruments may be used, for instance, forceps and probes, and operations can be performed as upon any other part of the body. Dr. Cohen showed an ingenious arrangement fn the handle of the tongue depressor by means of which any insufficiency in the light may be supplemented. This consist of a small electric light of twelve volts, with the aid of which and by means of a contrivance of a hood and prism the light is thrown horizontally along the tongue depressor. Not every patient will submit to the use of this instrument, as a good deal of pressure must be exerted; but as familiarity with it increases it will be available in a great many more cases than now seems possible. The instrument has the further advantage of showing the posterior wall of the larynx, while the laryngoscope reveals principally the anterior parts; thus one instrument supplements the other.

By invitation of the directors, B. ALEXANDER RANDALL, M.D., of Philadelphia, exhibited a large number of lantern views demonstrating

THE SURGICAL ANATOMY AND PATHOLOGY OF THE MASTOID.

REVIEWS.

DISEASES OF THE SKIN; Constituting the fifth volume of "Twentieth Century Practice; an International Encyclopedia of Modern Medical Science." Wm. Wood & Co., New York.

THIS volume is the work of various writers, including some of the leading authorities of Europe and America.

Like every production of multiple authorship, it is admirable in some parts and open to criticism on account of its weaker portions. The arrangement of the various classes of skin disease is hardly to be commended since it involves repetition in the discussion of some affections and no mention of others.

The work will doubtless be of value to dermatologists, who will find in it some facts which are new and important. To the physician in general practice, however, it will be somewhat confusing and far less instructive than any one of the recent standard works on dermatology. It can hardly be expected that he will appreciate a volume treating of "Pinta disease," an eruption confined chiefly to the tropical regions of South America. "Hodara's disease," a kind of trichorrhexis nodosa, which, Menahem Hodara says, is frequent among the women of Constantinople, and other rare dermatoses never seen and rarely heard of in America, to the exclusion of practical articles on ichthyosis, lupus vulgaris, and other common affections which he is often called upon to treat.

The work is well printed, and contains a few new and instructive illustrations.

PRINCIPLES OF BACTERIOLOGY. By A. C. ABBOTT, M.D. Third edition enlarged and thoroughly revised; 12 mo.; pp. 493. Published by Lea Brothers & Company, Philadelphia and New York.

THAT a third edition of this valuable work should be required in a little less than a year, is in itself evidence of its intrinsic merit, and in presenting this important subject in so compact and readable a volume, the author has placed not only the teachers of bacteriology, but also the whole medical profession under obligation to him. After presenting the most reliable methods of sterilization, the preparation of nutrient media and the isolation of bacteria, this volume proceeds to give a clear outline of experiments in and practical applications of the principles underlying this important department of medical knowledge. The biology of the more common pathogenic organisms is also given. As a text-book for students and beginners in the study of bacteriology, as well as for the busy practitioner, who desires a certain degree of familiarity therewith, this book can be unhesitatingly recommended. The style is condensed and succinct without sacrificing in any degree ease or clearness. The mechanical preparation of the book is to be commended, and the illustrations are good and helpful. Of these, seventeen are colored.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE PERIOD FROM JUNE 21, 1896, TO JULY 15, 1896.

PURVIANCE, GEORGE, Surgeon, to assume temporary command of service at Philadelphia, Pa., for thirty days, July 3, 1896.

PECKHAM, C. T., Passed Assistant Surgeon, placed on waiting orders, July 3, 1896.

WHITE, J. H., Passed Assistant Surgeon, to proceed from New York, N. Y., to Key West, Fla., for special duty, July 10, 1896.

VAUGHAN, G. T., Passed Assistant Surgeon, granted leave of absence for thirty days, July 7, 1896.

STIMPSON, W. G., Passed Assistant Surgeon, to assume temporary command of Service at Port Townsend, Washington, July 3, 1896.

SPRAGUE, E. K., Assistant Surgeon, to proceed from Boston, Mass., to New York, N. Y., for temporary duty, July 10, 1896.

WICKES, H. W., Assistant Surgeon, granted leave of absence for twenty-seven days, July 8, 1896.

GREENE, J. B., Assistant Surgeon, to proceed from Baltimore, Md., to Point Pleasant, N. J., for physical examination of crews of Life Saving Service, July 13, 1896.

JORDAN, W. M., Assistant Surgeon, to proceed from Birmingham, Ala., to New York, N. Y., for temporary duty, July 13, 1896.

PROMOTIONS.

NYDEGGAR, J. A., Assistant Surgeon, commissioned by the President as Passed Assistant Surgeon, July 7, 1896.

STEWARD, W. J. S., Assistant Surgeon, commissioned by the President as Passed Assistant Surgeon, July 8, 1896.

APPOINTMENT.

JORDAN, WILLIAM M., of Alabama, commissioned by the President as Assistant Surgeon, July 7, 1896.

VOL. LXIX. NEW YORK, SATURDAY, AUGUST 8, 1896. NO. 6.

ORIGINAL ARTICLES.

TECHNIC OF ABDOMINAL SALPINGO-OÖPHORECTOMY WITHOUT PEDICLE.[1]

BY T. J. WATKINS, M.D.,
OF CHICAGO;
GYNECOLOGIST TO ST. LUKE'S, PROVIDENT, AND LAKESIDE HOSPITALS.

A PAPER upon this subject would have been more acceptable before vaginal hysterectomy, vaginal salpingo-oöphorectomy, and vaginal incision and drainage had become well-established operations. Although these operations have a wide field of usefulness, abdominal salpingo-oöphorectomy is the operation of election in many cases of pelvic disease, and is, therefore, deserving of careful study. I believe that many of the unfavorable results which have followed abdominal salpingo-oöphorectomy have been due to faulty technic. The technic of the operation has been developed by so many surgeons that it is impossible to give each the credit due him, and to attempt to give the development of the operation in detail would unduly lengthen this paper.

I. CURETTAGE OF THE UTERUS.

This procedure should always precede abdominal section for the removal of the uterine appendages, because in these cases the endometrium is usually so diseased as to interfere with the recovery of the patient if this part of the operation is omitted, and because thorough cleansing of the uterus, vagina, and vulva, is imperative in case vaginal drainage is required.

The abdomen, vagina, and vulva, having been previously prepared, the vagina and vulva are again thoroughly cleansed under anesthesia. The uterus is then dilated, curetted, irrigated, and, if septic, packed with iodoform gauze. The vagina and vulva are then cleansed again in order to remove any septic material which may have escaped from the uterus during curettage. The pelvic organs are next carefully examined, and if any doubt exists as to the operation of election, an exploratory incision is made through the upper part of the posterior vaginal wall. The index finger is passed through this opening and the uterus and appendages are carefully examined. Great care should be taken to avoid rupture of an abscess into the general peritoneal cavity. If an exudate exists between the vagina and rectum, it is probably extraperitoneal, and should be evacuated through a vaginal incision and the cavity thoroughly cleansed and packed with gauze. If the exudate is not extraperitoneal, the swelling would not extend far below the point at which the peritoneum is reflected from the rectum to the uterus. If positive indications for abdominal incision exist, the vagina is sponged dry and packed with iodoform gauze, and the patient is placed in a moderate Trendelenburg position.

II. ABDOMINAL INCISION.

The abdomen having been thoroughly prepared is washed with ether, iodoform collodion is painted over the umbilicus, and an incision through the abdominal wall, two or three inches long, is made along the linea alba through the skin and subcutaneous fat down to the aponeurosis. The lower end of the incision should be at about the upper border of the pubes. If the uterine appendages appear to be fixed high in the pelvis, an incision of the same length should be made, but nearer the umbilicus. The aponeurosis is then incised, whereupon the sub-peritoneal fat is exposed, this may be separated with the finger or incised, whereupon the peritoneum will come into view. The hemorrhage is controlled by forci-pressure. The peritoneum at the upper end of the incision is caught on either side superficially by two forceps and elevated. If the fold thus formed is translucent it does not contain omentum, intestine, or bladder, and is incised between the forceps. The opening in the peritoneum is then enlarged, care being taken not to injure other structures. The peritoneal incision should never be carried down as low as the incision through the skin; this does not interfere with freedom of manipulation, and protects against the danger of injury to the bladder.

Should the incision through the aponeurosis enter the sheath of the rectus, as usually occurs, the inner border of the muscle may be found by pushing the handle of the scalpel along the upper border of the sheath on either side of the incision; then by placing the index fingers between the recti muscles, the tissues above the peritoneum

[1] Candidate's paper, presented for admission to the Am. Gynec. Soc., May, 1896.

may be easily separated the whole length of the wound. When the peritoneum is much thickened by disease, great care should be exercised in incising it. The incision is enlarged to facilitate the operation, when numerous adhesions or very large appendages are present.

III. SEPARATION OF ADHESIONS.

1. *Adhesions of Omentum.*—If the adhesions are not strong they are separated; if strong, they are not separated, unless the uterus cannot otherwise be reached. Adhesions are separated either by rubbing them between the thumb and index finger, or by pushing the omentum from the organ at the point of attachment with the fingers covered by gauze. None of the omentum is excised unless it is necrotic, or much thickened by inflammatory exudate. All bleeding points are carefully ligated with fine catgut or silk.

2. *Adhesions of the Intestines.* — Intestino-uterine adhesions are separated between the fingers or with gauze as described above. If the adhesions are so firm as to endanger the integrity of the intestinal wall, the peritoneum covering the uterus is incised above the point of adhesions, and the adherent portion of the peritoneum is separated from the uterus and left attached to the intestine. The intestine is not separated at the time from uterine appendages, or from the broad ligaments, because, I believe, less time is required and less danger of injury to the intestine is incurred by immediately proceeding to enucleation of the uterine appendages.

3. *Adhesions of the Uterine Appendages.*—If pus is present, the intestines are systematically walled off from the pelvis by the free use of gauze pads. In case of rupture of the abscess during the process of enucleation, a basin of strips of gauze should be ready to take up the pus as fast as it escapes. With the uterus as a landmark, the appendages are examined, and enucleation is commenced at the place where adhesions are least firm and fibrous.

If a large abscess with extensive firm adhesions exists, the pus is removed by aspiration, and the punctured wound closed by forceps, ligated, or protected with gauze. If during enucleation adhesions, which seem to be formed by a solid exudate, are encountered, great danger of rupture exists, because this condition always indicates points at which leakage of pus has occurred. Adhesions of this character should always be left until all fibrous adhesions have been separated, and if the abscess is large, should not be separated until the pus has been removed by aspiration. In severe cases, time can be saved and the danger of rupturing the abscess lessened by commencing the enucleation low down posterior to the uterus, or on the uterine side of the appendage. This is preferable to making the enucleation along the tube on the upper surface from the uterus as is still frequently recommended.

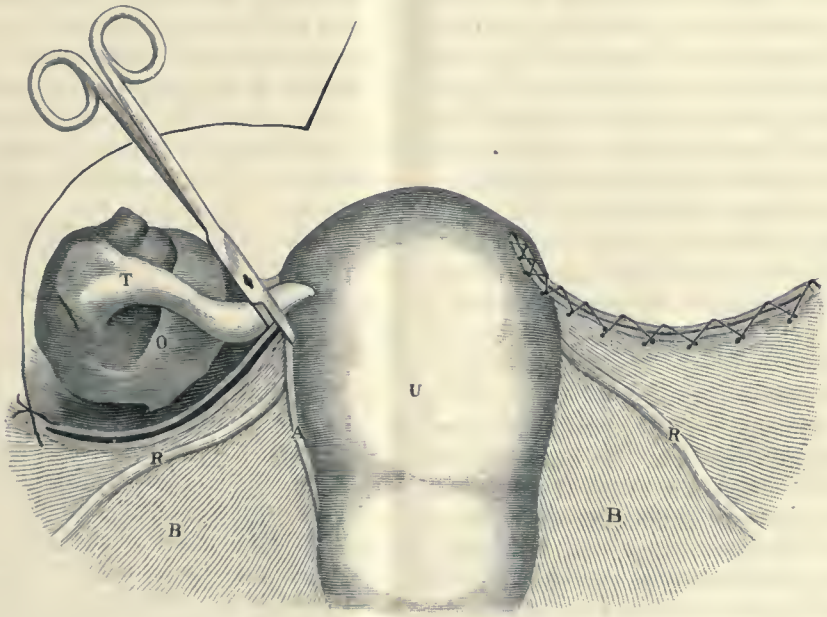
It should be remembered in this connection that tubo-ovarian abscesses are frequently posterior to the broad ligaments, and that they should be entirely rolled out from this location before attempting to bring them into the abdominal wound. When the appendages are free from adhesions to the uterus, broad ligaments, and pelvic wall, any intestinal adhesions which may be present, can usually be separated with surprising facility and safety. If adhesions of the intestines to the broad ligament exist, and are so firm that their separation will result in serious injury to the intestine, they should be left undisturbed. This method of enucleation, which must be accomplished largely by touch, is, I believe, far preferable to the separation of all adhesions under sight, which necessitates working from above downward. Some surgeons advocate the separation of all adhesions, and others believe in separating as few as possible, consistent with thorough removal of the diseased appendages. It would seem good surgery to break up all friable adhesions and to disturb the very firm adhesions as little as possible. The separation of firm adhesions frequently results in serious injury to the intestine, and the raw surfaces thus made are certain to become adherent, and the new adhesions may do more damage than the original ones. In a recent operation, after I had enucleated one appendage, it seemed impossible to enucleate the other on account of extensive and firm intestinal adhesions. After removal of the uterus, however, it was easily enucleated.

IV. EXCISION OF THE APPENDAGES AND SUTURE OF THE BROAD LIGAMENTS.

After all adhesions have been carefully separated, one of the appendages is raised into the wound, and the abdominal wall is retracted with a Simon speculum, or a broad, short retractor placed anterior to the broad ligament. A medium-sized catgut suture about eighteen inches long, armed with a blunt pointed needle about 1½ inches long, is then carried under the infundibulo-pelvic ligament just deep enough to include the ovarian artery. This suture is tied, the short end is cut off near the knot and the long end is left to suture the broad ligament. The tube and ovary

are next separated from the broad ligament by dividing the latter close to the tube from a point just external to the tube and ovary, and by continuing the division until the uterus is reached. All bleeding points are caught with forceps, and the uterine artery is clamped immediately underneath the tube before it is severed (see figure). The tube is excised flush with the uterus, or if its uterine portion is diseased, the dissection is carried into the horn of the uterus to a point beyond the affected portion.

The wound is then closed with the long end of the suture just mentioned, which was used to ligate the ovarian artery, by the glover's stitch, an assistant holding the end of the suture constantly taut. The stitches are inserted about one quarter



SALPINGO-OÖPHORECTOMY WITHOUT PEDICLE.
Left ovary and tube have been excised and wound closed by suture. Right ovary and tube separated from broad ligament, long end of suture left for closure of wound.

of an inch apart, and care is taken to bring the edges of the wound in as close apposition as possible, so as to leave little or no raw surface. If the broad ligament is friable, care should be taken not to make so much traction on the suture as to cause laceration of the tissues. The uterine tissue may also be lacerated by excessive traction on the suture. All or part of the ovary may be left if not diseased. The appendage of the other side is treated in like manner.

The suture above described has controlled the hemorrhage perfectly in every case in my experience. If the uterus is so diseased as to be likely to interfere with perfect recovery, it is amputated through the cervix, after the uterine arteries have been ligated, and the stump is closed by continuing the glover's suture from one broad ligament to the other. The only objection to suture of the broad ligaments is that it takes more time than is required for ligation of the pedicles, but this does not obtain in cases where the pedicles are very broad, or where the broad ligaments are friable.

The advantages of suturing the broad ligament are: (1) No pedicle is made. It is well known that the pedicle is liable to retract and cause hemorrhage, to become adherent to intestines, to remain painful, and to be a focus for infection and suppuration. (2) The entire tube and ovary can be excised. (3) Very little tissue is included in the suture and very little tension is made on the broad ligaments. (4) Little or no raw surface remains to form adhesions or cicatrices. (5) Absorbable sutures may be used without fear of hemorrhage. (6) Blood-vessels are ligated while in normal location, which protects against retraction and hemorrhage.[1] (7) When the broad ligaments are friable hemorrhage can be more easily controlled by suture than by ligature *en masse*. (8) Bleeding points in the posterior surface of the broad ligament are more accessible after suturing than after the broad ligament has been puckered by ligature. After the use of the ligature *en masse*, swelling frequently occurs about the pedicle or in the broad ligament, as the result of hemorrhage, or

[1] C. B. Penrose, *American Journal of Obstetrics*, August, 1895.

inflammatory exudate. So far as I know this has never occurred after the employment of this method of suture.

I have employed this method of suture in every abdominal salpingo-oöphorectomy which I have made since January, 1895, and I think the results have demonstrated its advantages. In only one case has bloody uterine discharge occurred after entire removal of the uterine appendages, and this was in a case of double pyosalpinx closely following abortion. A recent curettage in this case showed the endometrium to be thickened by glandular inflammation and stopped the hemorrhage.

Atrophy of the uterus has occurred, with the above exception, in all the patients I have examined several months after the operation. Many of the operations were, however, performed on hospital patients whom I have not had an opportunity to examine after they left the hospital. Of about seventy-five patients, two died soon after the operation from, I believe, profound septicemia, which existed at the time of operation.

Polk and Penrose advocate an operation similar in principle to the one described, though somewhat different in technic. Polk says:[1] "Using silk or catgut, as one may elect, the ovarian vessels are ligated *en masse* just outside the ovary and the fimbriated end of the tube. The tube is then dissected out as far as the cornu of the uterus, bleeding points being caught up and ligated as one proceeds, with catgut or fine silk. The ovary is next cut away, the bleeding points being treated in the same manner. As in all abdominal operations it is a prime object to present as few raw surfaces as possible, the raw surface left by removal of the tube and ovary should be covered up, if possible, by stitching back the round ligament to the line of the broad ligament, immediately below that just occupied by the tube; the tube should be amputated at the cornu by an oblique incision from behind, forward and inward, thus leaving a surface which can be apposed to the round ligament. . . . It will have been noticed that even in the radical removal of the appendages ligation of the tube is avoided. This is a measure to which the writer attaches great importance, because he believes that many of the recurrent symptoms to which the patients are often subjected are due to the presence of the ligature upon the tube." Penrose[2] has described an operation as follows: "The first ligature is passed through the broad ligament near the pelvic wall, securing the proximal portion of the ovarian artery. The second ligature may include the Fallopian tube if there is no disease of the isthmus, or it may be passed immediately beneath the tube if it be necessary to exsect the tube from the uterine cornu. With the ligatures thus placed, the tube and ovary may be completely and safely removed. Usually there is no bleeding from the portion of the broad ligaments between the ligatures. Any bleeding which does occur can be readily controlled by separate ligatures. It is not necessary to place both ligatures before cutting away the ovary and tube. The first ligature may be placed about the aproximal portion of the ovarian artery and then the infundibulo-pelvic ligaments may be cut, bleeding from the distal end being controlled with forceps. This will enable the operator readily to bring the ovary and tube through the incision, and to ligate the ovarian artery at the uterine cornu."

In the same number of the *American Journal of Obstetrics*, page 283, I briefly described this operation for the removal of the ovaries and tubes without a pedicle and presented a specimen.

V. CONTROL OF HEMORRHAGE.

Hemorrhage from separation of omental adhesions is immediately controlled by fine catgut or silk sutures, or ligatures. If in the separation of intestinal adhesions, hemorrhage occurs from laceration of the intestinal wall, the rent is closed at once with fine catgut sutures, which will stop the hemorrhage. General oozing from slight abrasions of the intestine, can easily be controlled by firm pressure with hot sponges or gauze. Active bleeding frequently occurs, while firm tubo-ovarian adhesions are being separated. This can usually be sufficiently controlled by firmly packing hot gauze or sponges against the bleeding surface. Should the hemorrhage persist, a forceps should be placed on the broad ligament external to the ovary and tube on the side from which the hemorrhage occurs, in order to secure the ovarian artery, and a forceps should be placed on the broad ligament at the cornu of the uterus to secure the uterine artery. Hemorrhage from the separation of uterine adhesions may be controlled with suture, but if after both appendages have been excised. hemorrhage occurs from numerous or extensive abrasions, hysterectomy should be performed. Hemorrhage from the pelvic wall may be checked with fine sutures or gauze packing.

VI. DRAINAGE.

The term "drainage," as here considered, refers to removal of fluid, to quarantining necrotic or

[1] "Clinical Gynecology," 1895, p. 579.
[2] *American Journal of Obstetrics*, August, 1895, p. 223.

infected tissue, and to tamponnade for hemorrhage. Drainage should be employed : (1) When general septic peritonitis exists. (2) When septic matter has escaped into the general peritoneal cavity. (3) When necrotic or septic tissue is left in the pelvic cavity. (4) When hemorrhage exists which cannot be readily controlled by ligature, suture, or temporary pressure. (5) When an intestine has been so injured that fecal fistula is liable to occur.

The vaginal route of drainage should be almost invariably employed in preference to the abdominal route because: (1) The most dependent portion of the abdomen is drained. (2) Drainage is downward. (3) The surface which usually requires drainage is in, more or less, close proximity to the vagina. (4) The danger of hernia is diminished. (5) Fewer adhesions must of necessity occur, as the abdominal cavity is kept more free from exudates. (6) The danger of infection of the abdominal wound is diminished.

In my experience, better results have been obtained with the vaginal than with the abdominal route of drainage. The statement frequently made that the vagina can not be made clean enough to drain through, is not substantiated by the results obtained from vaginal operations. Drainage through the abdomen is preferable: (1) When the surface to be drained is near the abdominal incision. (2) When the opening into the vagina can not be readily made on account of adhesions posterior to the uterus. (3) When septic disease of the vagina or vulva exists. Combined abdominal and vaginal drainage may be employed when indications for drainage by both routes are present. Gauze is the best material for vaginal drainage in almost every case.

I employ the following technic in the application of vaginal gauze drainage : Before the sponges which protect the intestines are removed, the patient is lowered from the Trendelenburg to the horizontal position, and the point of a long sharp-pointed scissors, curved on the flat, is pushed from the vagina into the peritoneal cavity posterior to the uterus. The blades of the scissors are then separated and withdrawn. With one finger inserted from the vagina, and one from the abdomen, the opening is dilated to the desired size. If the surface to be drained is large, the end of a piece of gauze, two feet wide and folded, is then carried into the abdominal incision out through the vaginal opening, caught by the finger or forceps and pulled out over the perineum. As little of the gauze as is required to cover the necrotic or infected tissue, or to stop hemorrhage is left in the peritoneal cavity. The punctured wound will not usually bleed unless the tissue is indurated. If hemorrhage occurs it may be necessary to pass a suture and ligate, or to use forci-pressure through the vagina. Little or no more time is required for the application of vaginal gauze drainage than for abdominal drainage.

When the slightest indication for drainage exists, I believe the vaginal gauze drainage should be employed because it is almost impossible for it to do harm, and it may do much good. If active drainage is required, the end of the gauze should project over the perineum so as to get siphonic action, and the end of the drain should be covered by a pad of gauze which should be changed as often as it becomes moist. The drain should be removed at the end of twenty-four hours if employed for hemorrhage, otherwise it may be left *in situ* for forty-eight or seventy-two hours. The operator should keep his hands scrupulously clean while inserting the drain, as well as in all the other steps of the operation. When general peritonitis exists, or when a large amount of infective fluid is present in the general peritoneal cavity, tubal drainage alone, or in conjunction with the gauze drainage, should be employed through the vagina.

VII. TOILET OF THE PERITONEUM.

With the patient in the horizontal position, all blood or serum is thoroughly removed by sponging out the pelvic cavity. The sponges covering the intestines are removed, and if necessary the pelvis is again cleaned by sponging. The abdominal cavity is not irrigated unless general peritonitis exists, unless a large amount of fluid has escaped among the intestines, or unless tubercular peritonitis is present. If the escaped fluid has been confined to the pelvis, it should be removed by sponges rather than by irrigation, because of the danger of carrying infection into the general peritoneal cavity. If irrigation is employed, a normal saline solution at the temperature of about 100° is probably the best to use, and the amount of fluid used should be sufficient to insure thorough cleansing. The fluid should be allowed to escape through the vaginal incision, as, after irrigation, drainage is a necessity. The omentum is then turned down over the intestines to prevent adhesions of the intestines to the abdominal incision. The omentum will possibly become adherent to the wound, but this is less objectionable than adhesions of the intestines to the wound. When the patient is exhausted from hemorrhage, and when the abdominal cavity is

not infected, as occasionally occurs in cases of rupture of ectopic pregnancy, it is a good practice to leave blood in the cavity or fill it with normal saline solution for absorption.

VIII. CLOSURE OF THE ABDOMINAL WOUND.

The accidents that most frequently follow closure of the abdominal wound are suppuration and hernia. The former now seldom occurs. The causes of suppuration are infection from contact with pus or septic tissue, from faulty technic in the closure of the wound, from the employment of drains, and from meddlesome after-treatment of the wound.

When the wound becomes infected by contact with pus or septic tissue, it should be thoroughly sponged with sterilized water, or with weak antiseptic solution, not strong enough to produce necrosis of the tissue. I have seen cases in which, I believe, suppuration resulted from the use of solutions of 1–1000 bichlorid of mercury. When the wound has been infected, buried sutures should be avoided on account of the danger of suppuration, the wound should be closed by sutures, which include all the layers of the abdominal wound, and the aponeurosis should be accurately coaptated by the additional use of quilled sutures. In an infected wound, sutures, such as silkworm-gut, or silver wire, which have no capillary action, should be used. If the abdominal wall is very thick, a drain may be used for a short time between the skin and aponeurosis, or preferably the superficial part of the wound may be left open and packed with gauze for twelve hours, and then carefully closed by tying sutures placed at the time of the operation. The aponeurosis, muscles, and peritoneum are closed, before the packing is inserted, by quilled sutures.

When suppuration occurs in a wound which has not been exposed to septic fluid or tissue, the sepsis must be due to faulty technic in closure.

The use of vaginal drainage in cases which would otherwise have required abdominal drainage, will eliminate one of the principal causes of suppuration in the abdominal wound. Infection may occur from unnecessary changing of the dressings or washing of the wound. When no abdominal drain is used, the gauze over the wound may be changed at the end of twenty-four hours if much soiled, but the wound should not otherwise be disturbed until the time for the removal of the sutures, unless symptoms indicate suppuration. Hernia may result from incomplete primary closure of the wound, from inaccurate coaptation of the aponeurosis, from suppuration in the wound, from the patient getting up too soon after the operation, or from non-use of an efficient abdominal supporter.

Incomplete primary closure of the wound always occurs when abdominal drainage is employed, and is especially noticeable when the Mikulicz drain is used. The abdominal drain is necessary only in exceptional cases, and, I believe, that the vagina offers a better route of drainage than the abdomen in nearly all cases, when considered either from a theoretical or a practical standpoint. When the abdominal drain is used it should be removed as soon as the discharge ceases, and the wound should be closed by tying sutures which were placed at the time of the operation, if the cavity drained is not a suppurating one, or does not contain necrotic tissue.

Incomplete coaptation of the aponeuroses probably always occurs to a greater or less extent when the "through and through" suture is used. When the wound has not been infected, the peritoneum should be closed with a fine continuous catgut suture, and the fascia, external to the recti muscles, should be accurately coaptated. "This is the most important step in the closure, as in this fascia lies the strength of the abdominal wall, and in this proper reunion lies the protection against hernia." [1]

When the wound is aseptic this should be accomplished by means of buried sutures, or by quilled sutures. Either catgut, kangaroo tendon, silkworm-gut, or silver wire, may be employed for buried sutures. It has not yet been determined which of these suture materials is preferable. I believe that the muscles should not be sutured, because to suture them causes an unnatural union which has no material strength and which must interfere with their action. Suture of the muscles also increases the pain in the wound. It causes atrophy from including parts of the muscles in the sutures and from union of muscle-fibers. The strong aponeuroses in an infected wound may be accurately coaptated by the quill suture. The skin and subcutaneous tissue are united by silkworm-gut sutures.

HYGIENIC PRINCIPLES IN THE PREVENTION OF EAR DISEASES.

By PERCY H. FRIDENBERG, M.D.,
of New York;
Assistant Surgeon, New York Eye and Ear Infirmary.

The prevalence of acute and chronic nasopharyngeal affections under local climatic conditions of rapidly varying temperature and humidity, the frequency and danger of complicating

[1] "American Text-book of Gynecology," p. 79.

diseases of the organ of hearing, and the common neglect of hygienic measures, which are, for the greater part, simple and effective, offer sufficient reason for my submitting a rew remarks on the subject. Under normal conditions of health, the organism may give shelter to many microbes, some of them pathogenic in nature. The latter are held in check by the vital antisepsis of the blood, the energy of the cell, and the power of resorption and metabolism of the organs. A further defense is afforded by the impermeability to germs of the normal epithelium, and by the antagonism existing between different species of microörganisms or their respective physiological products.

The commonest path of aural infection is from the nasopharynx through the Eustachian tube. Under normal conditions, the reflex action of swallowing causes the renewal of air in the tympanic cavity. If this automatic ventilation be disturbed, the consequences soon become unpleasantly apparent in a diminution of hearing. The physiological ventilation may become a source of danger, to which are added other and more violent reflex movements, such as coughing, sneezing, or vomiting. These reflexes overcome the muscular bar of the Eustachian tube and cause a sudden rise of air-pressure, which, though but momentary, is strong enough to force into the middle ear some material from the nasopharynx, as mucus and any microörganisms that may be present. As evidence of this, the frequency of middle-ear complications in epidemics of acute and subacute nasopharyngeal affections may be cited; but without any mechanical assistance, pathogenic organisms may traverse the tube and produce the tympanic complications not unfrequently observed in pneumonia, typhoid, scarlet fever, and other infectious diseases.

Less frequently, but no less certainly, the blood carries the agent of infection to the affected organ of hearing, or inflammatory products may be transported and become lodged in the terminal blood-vessels of the middle ear, as is not unfrequently the case in septic endocarditis and in pyemic conditions. Finally, we must not forget that a possible, although rare, mode of infection is offered by the presence normally, as observed by Zaufal, of pathogenic germs in the tympanic cavity, which may, under favorable circumstances, become virulently active. Besides these internal paths, the ear may become affected from without, as it most frequently is in disease of the external ear, and as complications of deeper parts. Injuries and inflammatory processes of the auricle and meatus may affect only the external ear and the adjacent structures, or may cause general infection; again, the inflammatory process often extends to the barrier between external and middle ear, with destruction of the drum membrane and rapid development of middle-ear inflammation. Even without perforation of the tympanic membrane, the pathogenic process may penetrate, by means of blood and lymph channels, to the deeper structures.

A knowledge of the methods of aural infection should guide us in our therapeutic and prophylactic measures. First and foremost is the importance of a proper hygiene of the nasopharynx, in health as well as in disease. The care of the mouth and pharynx is so habitual, and its importance so obvious, that it might seem superfluous to call attention to the necessity of keeping the teeth clean and the recesses of the mouth and throat free from all foreign matter. Unfortunately this is not the case. These manipulations are frequently neglected through ignorance, or they are performed at irregular intervals and in an incorrect and inefficient manner. A perfunctory brushing of the teeth on rising in the morning, and so-called gargling with a few drops of a mouth-wash are considered by many sufficient for the subsequent twenty-four hours, and the products of fermentation and decay, with the microörganisms, are left undisturbed for a whole day. Besides this, the conditions for decomposition are made more favorable by the conditions of the mouth and nasopharynx during sleep. The rational deduction is that the most careful cleansing of teeth should take place at night and again on rising, for in spite of all such measures, the buccal cavity will be found full of microörganisms in the morning, and perhaps a less careful toilet of the mouth should follow each meal. If these simple, hygienic measures were systematically and energetically applied, especially in childhood, we might hope for fewer complaints of foul breath, weak stomach, or decayed teeth; not only this, but the mucous membrane of the mouth and pharynx would become toned and strengthened against many infectious diseases. The most important prophylaxis in any epidemic is the care of the buccal cavity. Lavage of the throat is so carelessly done as to be in most cases practically useless. The fluid at most rinses the mouth, and does not reach the back of the pharynx, the tonsils, etc. Besides this, the method is a false one and its results a failure. Tough mucus cannot be removed in this way, even if the fluid did reach the deeper parts. A more rational pro-

cedure is the pharyngeal douche. A small amount, not a mouthful, of fresh, cold water should be used. The chin is now raised and the fluid allowed to run slowly back by its gravity, without any attempt at gargling. When the fluid reaches the lowest part of the pharynx, it causes a sudden, brisk, reflex contraction of the pharyngeal muscles, which, assisted by a forward inclination of the head, is amply sufficient to empty the contents of the mouth. This simple process may be repeated three or four times. By this method the lower portions of the throat are reached, and above all, the energetic spasmodic muscular action effectually dislodges all tough adherent mucus. Where there is a tendency to catarrh or sore throat, antiseptic solutions may with advantage be substituted for pure water. In addition to these local measures, we must consider the value of regular exercise, fresh air, cold baths, pulmonary hygiene, and breathing exercises.

However we may be disposed to neglect these procedures in health, the presence of local or general disease increases our responsibility and the necessity of rational hygienic measures. Nasal or pharyngeal catarrh, whether idiopathic or symptomatic of measles or scarlet fever, is frequently complicated by acute middle-ear affections. The disease brings with it the necessity of freeing the nasal cavity at frequent intervals, and the simple blowing of the nose, if violently or carelessly done, as is usually the case, may be a source of danger. It should be done as seldom as possible, as violent blowing only adds to the existing irritation and congestion. If this is not sufficient, the mucus must be made less consistent and removed by an alkaline douche. Both nostrils should never be closed at once, and no hairpin or similar utensil should be used. Therapeutic measures, which occasion a local rise of air-pressure, such as Politzerization or the use of the Eustachian catheter, are distinctly contraindicated during the acute stage of such affections, especially if there is complaint of pain in the ear. The pain often indicates that there is already a congestion or inflammation in the tympanic cavity, and these procedures may drive the infecting matter into the recesses of the mastoid with the most serious results. We must be on our guard in the case of infants and little children, and consider at all times the possibility of ear complications when restless sleep, peevishness, and crying might suggest intestinal parasites, colic, teething, or what not. Frequently a discharge from the ear is our first intimation of the real state of affairs. In such cases, as in the case of apathetic or comatose patients, in typhoid, pneumonia, meningitis, and similar diseases, the ear-drum should be frequently inspected. In chronic affections of the nasopharynx, aural complications are so frequent as to be the rule. Chronic hypertrophic catarrh, with adenoid vegetation in the pharyngeal vault, is notable in this respect. Digital exploration is usually the simplest and most effectual diagnostic method, as posterior rhinoscopy may be impracticable with unruly or frightened children. The local action of adenoid hypertrophies may cause a direct affection of the Eustachian tube by occlusion of the pharyngeal ostium and consequent retraction of the drum by rarification of air in the tympanic cavity, or their presence may cause repeated attacks of catarrh, which sooner or later extend to the middle ear. The breathing is affected markedly, and hearing not infrequently diminished. Although forced to operate in most cases, much may be done in mild forms by insistent local treatment. Direct application to the nasal passages of weak nitrate of silver solutions or of iodin-glycerin, five to ten per cent., act well in almost all cases, when used at an early stage. The reaction may be severe, however, and for this reason it is advisable to apply the solution to one passage only in each sitting. The cotton pledget should be tightly wound on an angular carrier or forceps, and there should not be enough fluid to allow any dripping into the pharynx. Two or three days should elapse between each application. The nasal douche is decidedly inapplicable here, as in all cases of nasopharyngeal obstruction fluid easily enters the Eustachian tube, and may be aspirated into the middle ear. Massage of the nasal mucous membranes has been advocated, and good results claimed for it by several authors.

The use of a nasal douche should be governed by a few simple, but stringent rules, if it is to remain a beneficial measure and not become a source of danger. The bulb of the fountain syringe, if this is used, should be directed horizontally backward, not upward, the bag hung not more than one foot above the nasal passage. The head should be inclined forward slightly, with the mouth open, and the douche fluid slightly warmed. The nasal douche-cup or spoon is even better than a fountain syringe, or the fluid may simply be snuffed up from the palm of the hand.

The necessity of removing hypertrophic tonsils is self-evident as a prophylactic measure against ear disease. Similarly, congenital fissure of the hard and soft palate should be treated.

A consideration of all the possible causes of

aural affections brings us finally to the communication from without through the external auditory meatus. Inflammation of the auricle or meatus may be propagated directly by extension or by transportation in blood- or lymph-channels. The custom of piercing the lobule for wearing of ear-rings has been responsible for many cases of this nature. A greater menace lies in the careless or incorrect cleaning of the meatus. The majority of instruments used for this purpose—ear-spoons of metal, rubber, ivory, or bone—are of doubtful utility, or absolutely dangerous. Small sponges on holders are a source of infection, rather than of asepsis or cleansing. The ear-spoons, especially those of metal, easily cause abrasions of the epithelium and small erosions, which may become infected and result in furuncles or phlegmonous inflammation. The use of an ear-douche is but little better. The epithelium is soaked and macerated, and when dry becomes a source of irritation. Oil, glycerin, and other substances of a similar nature are inappropriate, on account of their tendency to become rancid. The most rational method of cleaning, which is perfectly thorough, may be accomplished by using a small tuft of absorbent cotton, not a large pledget, tightly wound about a blunt and smooth wooden tooth-pick, the end being left loose and fluffy. In case the cerumen is hard, the cotton may be lightly dipped in soap-water or moistened with a drop of ether. Another source of serious inflammation of the ear is the presence of foreign bodies in the external meatus, and more particularly unskilful or violent attempts at their removal. Instruments are never to be used in these cases, especially when the foreign body is hard or brittle, as they invariably fail to grasp and push the offending object still deeper into the ear. Our sovereign remedy here consists in syringing, and is effectual in nearly all cases, unless the foreign body is very voluminous or has entered the ear with great force. Under these conditions extraction under a general anesthetic may be our only expedient. Injuries of the ear not infrequently produce a rupture of the drum, whether caused by a blow or entrance of a foreign body, or by sudden change in atmospheric pressure. Here, too, the original lesion may be less dangerous than misguided therapeutic efforts. All washing, syringing, or instillations are contraindicated, at least directly after the injury. If the rupture can be seen, a loose tampon of absorbent cotton is all that is needed. In case there has been a free hemorrhage and our view is obstructed, the blood-clot may be gently wiped away with cotton on a holder. The patient should be cautioned to avoid all procedures which would cause a rise of air-pressure in the tympanic cavity, and especially to use no force in blowing the nose. The use of syringes is unequivocally condemned. Prompt healing will generally take place under the aseptic blood-clot, if this be left undisturbed. Even after a discharge has begun, much more can be accomplished by dry-cleansing by mopping with cotton or gauze, than by flooding the passage with fluid. The warning against syringing must be especially marked in case of serous discharge, where traumatic communication with the cranial cavity may reasonably be suspected.

Another source of danger, although of a less serious nature, is the common tendency to alleviate toothache or facial neuralgia by the use of hot oil, pledgets of cotton dipped in chloroform, oil of cloves, or other counter-irritants placed in the auditory canal.

In health we need also guard against the mechanical injury of the heavy surf at our sea-side baths. Complaint of fulness and pressure in the ear after bathing, with diminution in hearing, is usually due to the swelling of cerumen by the action of the water. The symptoms promptly subside when the wax has been syringed out. Even in case of an old perforation of the drum, the patient need not be deprived of the hygienic benefit and pleasure of sea-bathing. We need only suggest plugging the meatus with cotton, which has been partly dipped in oil. If we neglect this, the entrance of sea-water may be followed by an acute empyema of the mastoid, or by the relapse of an old discharge.

NEPHRITIS IN CHILDREN.[1]

By HENRY E. TULEY, A.B., M.D.,
of Louisville, Ky.;
Clinical Assistant to the Chair of Practice and Instructor in Physical Diagnosis in the Kentucky School of Medicine; Visiting Physician to the Masonic Widows' and Orphans' Home.

Much more attention has been paid to the consideration of this disease in late years than heretofore, but even now there is very little to be found in the literature bearing upon the subject; this is particularly the case in primary nephritis occurring in children.

A nephritis may be primary or secondary, the former occurring infrequently. It, however, does occur, though denied by some authors. It may be secondary to any of the exanthemata, perhaps more frequently as a sequel to scarlet fever, rheu-

[1] Read before the Kentucky State Medical Society, Lebanon, Ky., June 10, 1896.

matism, erysipelas, acute and chronic intestinal diseases, vaccination, and pneumonia, the active causative agent in these diseases being either of primary bacterial origin or the result of the elimination of their toxins by the kidneys.

The lesions of a nephritis may be classed as a "descending nephritis,"[1] the essential change being glomerular and epithelial, due to chemical, bacterial, or toxic agents. The other form may be called the "ascending" variety, due to invasion from the urinary organs below. This affects first the papillæ, and, by means of the lymphatics, the parenchyma is invaded, the change being toward the cortex.

In the interstitial form there is an accumulation of cells between the tubules; the kidney is large, moist, whitish, and opaque. Clinically, this form is a result of the exanthemata, and may give rise to few symptoms. The glomerular form is much more frequently found as a result of scarlet fever than the former. The lesion is chiefly a proliferation of the capsular epithelium, with hyperplasia of the connective tissue. This form is well called capsular glomerulo-nephritis. Councilman states that the acquired or primary form of nephritis differs but little from that in the adult, though children are less prone to the circulatory disturbances found, especially in the chronic form, in the adult. In the text-book by Ashby and Wright, it is stated that the lesion in acute nephritis of childhood is of the croupous pneumonia type; the blood-vessels are engorged, choking of the tubules results, and there occurs an exudate of the liquor sanguinis and blood-corpuscles. The inflammatory changes, failing to be relieved, secondary changes occur, the most important being a glomerular and peri-glomerular nephritis.

A very valuable contribution to the etiology of this disease has recently been published by Dr. A. Jacobi,[2] in which many valuable suggestions are made as to the causation of this ordinarily unlooked-for disease of the newborn.

While chiefly secondary in early infant life, the nephritis may be primary, or at least occur without any cause being patent, and as the child approaches puberty, partake more of the form found in adult life. It is a much more common disease than is generally thought, and would be recognized oftener if more systematic examination of the urine of infants and children was made. Urine can always be obtained, as catheterization at this age can readily be done. Exposure to cold or wet being the cause of a sudden change in the circulation, may be an exciting cause of the primary form, Lassar having proved the causation of interstitial and parenchymatous inflammation by sudden refrigeration.

[1] Gaillard's *Medical Journal.*
[2] *New York Medical Journal*, January 18, 1896.

Under this head may be mentioned sea-bathing and swimming in fresh-water streams, the long exposure to the cold water being often an exciting cause little thought of. This, Danforth[1] states, is the case in adults, but not in childhood. Money[2] states that "spontaneous Bright's disease must be admitted." Rotch[3] says that, with the exception of its occurrence in scarlet fever, diphtheria, and measles, the disease is not frequent.

In no disease of childhood are the symptoms so varied as in nephritis. They may be so trivial as to pass unnoticed, especially when there is neglect in the examination of the urine. In well-marked cases the symptoms are pronounced and aggressive; the younger the patient, the more prominently the symptoms may point to the brain, or perhaps to the gastro-intestinal tract, or to the lungs, thus obscuring the diagnosis of the true nature of the disease.

The onset generally is sudden, preceded by a chill and a rise of temperature to 102 or 103°; the pulse is very rapid, as a rule, and the tension is high. Convulsions may precede active symptoms or perhaps supervene later. Edema occurs early, and its presence should at once excite suspicion; at first the dorsum of the feet, the ankles, and legs are affected, then the face, general anasarca occuring in some cases. Blindness may frequently be seen, due to a retinitis, either simple, hemorrhagic, or colloid. Fox[4] writes that in the hemorrhagic and colloid varieties of retinitis albumin is not found in the urine, this is especially so of the hemorrhagic variety, which is considered a forerunner of a non-albuminuric Bright's disease. The urine is scanty and high-colored, though there may be suppression, but catheterization will generally obtain enough urine for an examination.

Albumin in large quantities is usually found; microscopic examination shows granular, epithelial, and blood-casts, and blood-cells. Anemia is prominent; the skin, which is of a peculiar waxy look, is dry and hot. Cough is not an infrequent symptom, and may be distressing if pulmonary edema develops to any extent. Pain, heaviness, or a sense of discomfort in the back may be complained of by older children. Headache is also prominent. Restlessness and disturbed sleep, involuntary cries, convulsions, and even coma are not uncommon symptoms; strabismus and dilated pupils are found frequently.

Of all the diseases of childhood, nephritis demands

[3] *Pediatrics.*
[4] MEDICAL NEWS, May 23, 1896.

the most prompt, vigorous, intelligent, and careful treatment. Three essential rules in the treatment must be recognized, viz.: (*a*) Relieve the kidneys of the extra work of carrying the transuded serum from the tissues, as well as the retained products of tissue metamorphosis usually excreted by the kidney and retained because of their damaged state; (*b*) endeavor, by intelligent medication and diet, to prevent further damage to the diseased organs; (*c*) restore the kidney to its normal condition.

In meeting the first indication, resort must be had to the compensatory emunctories, the skin and the bowels, and at no age can we rely upon them more than during early life. Calomel is indispensable. It stimulates the liver to action, and by the increased flow of bile the contents of the bowel are rendered more fluid and the elements to be excreted more soluble in the blood, thus proving less irritating to the kidneys. The salines are of great service as hydragogues.

Hot-air baths must be relied upon for their diaphoretic action, as pilocarpin is very uncertain and not to be depended upon. The best method of applying heat is by using an apparatus which will supply hot air under the bedclothes. This can be used continuously, as it does not cause prostration. Liquid ammonia acetatis is an efficient remedy in the stage of convalescence, acting beneficially upon the kidneys and the skin. The high tension in the arteries can be combated more efficiently by blood-letting than otherwise, its beneficial effect being seen upon the pulse, the nervous system, and the kidneys by lowering the blood-pressure.

A very valuable agent is water, given, perhaps, plain after filtration or boiling, as young children take carbonated waters with reluctance. Given *ad libitum* and at regular intervals, if the patient does not call for it, it acts as a diuretic, without causing any irritation. If refused by the mouth, it acts well as enema if large doses are given.

The following history is reported as being illustrative of the subject under discussion:

D. M., aged eleven years, an inmate of the Masonic Widows' and Orphans' Home, resident at the Home nine months; had always been a healthy child. On October 12, 1895, she reported to the nurse because "she was getting fat in the face." There had not been any outbreak of contagious diseases at the Home, and the patient's skin was perfectly free from any evidences of disease. She had been well up to the time of admission to the infirmary, and the edema was noticed now for the first time. She was put to bed, but was not reported as sick until the following day. At this time there was marked edema of the face and of the feet and ankles. A specimen of her urine was ordered saved, and she was put on milk diet pending the examination.

14th. At 8 A.M. she had a general convulsion, followed in the next three hours by five more. In the interval between the convulsions there was nystagmus and twitchings of the muscles about the eyes. There was one more convulsion during the day, but the only nervous manifestations during the night were the twitchings as above described. She was very restless when awake, and complained of great pain in the head. There was complete blindness at this time, and Dr. W. B. Pusey, Visiting Oculist to the Home, was called in to make an examination. He reported that the examination was very unsatisfactory, owing to the nystagmus and restlessness; no satisfactory view of the fundus was obtained. When the child had been dismissed, however, he found the fundus sound and the vision normal.

The pupils were well dilated and equal. The edema was quite marked, especially about the face, eyes, and lower extremities. Skin was hot and dry; pulse 160, full and bounding; the maximum temperature was 103°. Thirteen ounces of urine were passed in the twenty-four hours. It was high-colored, examination showing three-fourths per cent. albumin by volume, blood-casts and blood-corpuscles.

As soon as possible after the convulsion she was given ten drams of a saturated solution of Rochelle salts at intervals, and one-quarter of a grain of muriate of pilocarpin in equally divided doses, four hours apart, but no effect, either upon the skin or the salivary glands, was produced. Eight grains of calomel were given during the twenty-four hours, with a large movement resulting. She vomited twice after administering the calomel. She was put in the hot-air bath at this time, but no effect was noticed until the following day.

15th. Passed a restless night, twitching about the eye being noticed frequently. Pulse 160, and of high tension. At this time phlebotomy was done, about one ounce of blood being removed from the right median basilic vein. The effect of this withdrawal was almost immediate; the pulse fell to 104, there was less tension, and the patient seemed brighter, having taken no notice of the phlebotomy. Eight grains of calomel were given during the rest of the day, twenty-two ounces of urine were passed, and she had three movements, as a result of several large rectal injections given through the day.

16th. Rested well; complains of sore throat; coughs a great deal; examination of the chest proved negative. Vision returning slightly; can distinguish large objects and begins to recognize faces. Examination of the urine showed about one-third albumin by volume, a few granular casts, blood-corpuscles, and kidney epithelium. Given

one ounce of the saturated solution of Rochelle salts at intervals and one teaspoonful of liquor ammonia acetatis every three hours. Passed twelve ounces of urine and vomited three times.

17th. Rested well; edema rapidly subsiding; still coughs. Passed twenty-three ounces of urine and had two watery stools. Specific gravity of urine 1015, with some albumin, but much less than at the last report.

18th. Slight sweat in the morning. Passed forty-one ounces of urine.

19th. Cried nearly all night with pain in throat; nothing pathological visible. Passed thirty-seven ounces of urine; had three watery stools. Put on tincture ferri chloridi, six minims every three hours.

20th. A necrotic area of mucous membrane found on the right soft palate, extending down to the tonsil, about half an inch square. This is exquisitely painful and has a foul odor. Persulphate of iron applied every two hours. Passed twenty-four ounces of urine.

21st. Throat much better. Passed twenty-seven ounces of urine.

The following is a list of the amount of urine passed in the next few days: 22d, thirty-two ounces, specific gravity 1014, some albumin and blood-corpuscles; 23d, thirty ounces; 24th, forty ounces; 25th, forty-two ounces, albumin, granular casts, and kidney epithelium; 26th, forty-four ounces; 27th, fifty-two ounces; November 1st, urine clear and free from albumin.

Under tonic treatment with muriated tincture of iron and nourishing diet, the little patient improved rapidly and was dismissed from the infirmary in ten days, well. It is interesting to note that during the succeeding month she was one of ninety to have German measles, a mild attack, the urine remaining normal throughout.

The following points are of interest in connection with the above history: Pilocarpin muriate, a perfectly fresh preparation, to the total dose of one-quarter of a grain, did not have the slightest effect upon the child's skin or salivary glands, and did cause some depression of the circulation. Hot air had little effect in inducing elimination by the skin until it had been kept up for at least twenty-four hours. Calomel proved an efficient aid in elimination by the bowel, with the aid of Rochelle salts, which were borne by the stomach better than the calomel. Blood-letting was of the greatest benefit, not only upon the heart, reducing it from 160 to 104, and lessening the blood-pressure; also ridding the blood of a quantity of toxins at once. This is a remedy that should not be forgotten.

The case illustrates the remarkable recuperative power of the child, not only in surviving such overwhelming poisoning of the system, but the kidneys regaining their former integrity.

THE DISINFECTION OF BOOKS BY VAPOR OF FORMALIN.

By ELMER GRANT HORTON, B.S.,
THOMAS SCOTT FELLOW IN HYGIENE, UNIVERSITY OF PENNSYLVANIA.
(From the Laboratory of Hygiene, University of Pennsylvania.)

A GREAT deal has been written recently concerning the use of formalin as a preservative, antiseptic, and disinfectant. Investigators unite in acknowledging that it possesses these properties, while they differ in opinion as to the degree of efficiency, especially in the case of disinfection.

Dr. John S. Billings, Director of the Laboratory of Hygiene, University of Pennsylvania, proposed to the writer the testing of the efficiency of formalin vapor as a disinfectant for books, and also for rubber and surgical instruments. The writer wishes to here express his thanks to Dr. Billings, and also to Dr. A. C. Abbott, First Assistant, Laboratory of Hygiene, University of Pennsylvania, for their kind advice and timely suggestions during the course of this investigation.

We would naturally expect that books, particularly those of public libraries, passing through many hands under various conditions, would need disinfection; for at times they are handled and read by persons afflicted with infectious diseases, and may therefore serve as channels through which the disease may be disseminated. Nor is this now a matter of conjecture for Du Cazal and Catrin[1] have shown that books may be the vehicles of contagion. The results of their experiments were positive for the diphtheria bacillus, streptococcus, and pneumococcus, although negative for tubercle bacillus and bacillus of typhoid. There are numbers of cases of scarlet fever in which the source of infection is reasonably believed to be a book or letter.

In some places, as in parts of England, the only remedy for infected books has been destruction by fire. This waste of books, often valuable, may be averted if disinfection can be otherwise thoroughly accomplished. Messrs. Du Cazal and Catrin propose as a means of disinfection, the sterilization of the books by the autoclave, with the exclusion of bound volumes and board covers, which are injured by this treatment. Miquel,[2] in his efforts to obviate this difficulty, used a strip of cloth 15 to 20 cm. wide, attached at the ends to rollers, around one of which the cloth was wound and dipped into a solution of formalin, whose specific gravity had been raised from 1.075

[1] *Annales de l'Institut Pasteur*, Decembre, 1895, p. 865. "De la contagion par le livre."

to 1.2 by the addition of calcium chlorid crystals. This cloth was spread directly beneath a frame or rack holding the books, with the edge of the leaves downward. Cloth, rack, and books were then covered by a large jar, and at the end of twenty-four and forty-eight hours were found to be sterile. Van Ermengem and Sugg[1] found that in a closed vessel, sterilization was effected in twenty-four hours by sprinkling the leaves of an infected book. They found that books were not disinfected in a closed chamber after twenty-four hours if a weight of two kilograms rested on the books; but they obtained positive results in twenty-four hours if a vacuum was produced, and then air, saturated with formalin, admitted. In their experiments with elevated temperatures, these investigators found books were disinfected at a temperature of 60° C. in twenty-four hours with formalin. As a result of their researches, Van Ermengem and Sugg consider books as difficult of disinfection. Lehmann[2] agrees with them in this conclusion.

It was our intention to test as simple a method as possible, and yet one that was efficient. It would not be a practical matter to retain for several hours a temperature as high as 60° C. (140 F.), especially for large spaces. The following experiments were accordingly conducted at room temperatures varying from 19° to 31° C. (66.2° to 87.8° F.). The vapor was obtained by simple evaporation, and not by the burning of methyl alcohol, nor was addition made to the formalin of calcium chlorid or any other substance. The solution used was received from the firm of Bender & Hobein, Munich and Zurich, and had the specific gravity 1.084.

The action of formalin upon the anthrax spore has been determined by others. As neither *B. anthracis* nor its spore are apt to occur in books, this organism was not employed in our experiments. Virulent cultures have been used of *B. typhi abdominalis*, *B. diphtheriæ*, and *staphylococcus pyogenes aureus*, all of which are likely to occur in books.

The following was the method pursued: To avoid injury to the books by the cutting of the leaves, a sheet of paper was given a single fold, and between the two leaves thus formed, was placed a piece of paper 2 cm. square. After sterilization by dry heat of the sheets with their enclosed squares, they were placed in a book at desired pages, and the squares smeared with a twenty-four-hour-old bouillon culture of the organism in question. Drying of the culture was accomplished in from one to two hours, by placing the book in the incubator, 37° C. (98.6° F.). At this point, control cultures were made from the squares. The book was then placed under a bell-jar of known capacity. No weight rested upon the books except in few cases, when other light books were on top. Sometimes the books were stood on end, again they rested on the side, always closed. A measured amount of formalin was placed in a shallow glass dish under the bell-jar, and allowed to evaporate—the surface of evaporation varying from 26 to 70 sq. cm. After removal from the exposure to formalin, the books were allowed to stand for various periods of time protected from dust. At several dates after the exposure, portions of the square were placed in bouillon at 37° C. (98.6 F.), and observed daily for some time.

The questions presented were:

1. Can books under simple conditions be disinfected by the vapor of formalin?

2. What is the maximum amount of air per c.c. of formalin that may be used and yet the books be sterilized in a limited time—as twenty-four hours?

3. Will a shorter exposure than twenty-four hours suffice?

4. Will an increase in the length of time of exposure counterbalance a decrease in the amount of formalin employed?

SERIES I.—Length of exposure, twenty-four hours. Books of from 150 to 870 pages, mostly octavo books of 200 to 400 pages. Dates of experiments extending from March 11 to June 1, 1896. Controls all positive; g=growth; o=no growth.

c.c. of air to 1 c.c. of formalin.	Designation of experiment.	B. typhi abd.		B. diph.		Staph. p. aur.

500	h	.....	.....	.....	.....	3	g

[1] In these three tests a growth was obtained a few hours after removal from the vapor, but succeeding trials from the same square after two days or more were negative. This raised the question as to whether the vapor of formalin had condensed between the leaves and thus given a prolonged exposure after removal. Accordingly, parallel experiments were made, differing only in that the books were opened and exposed to air at the inoculated places as soon as removed from the bell-jar. The same result as previously observed made it clear that it was a case of weakened vitality in the organisms.

SERIES IV.—Exposures fifteen minutes. Octavo books of 130 to 732 pages. Controls all positive.

c.c. of air to 1c.c. of formalin.	Designation of experiment.	Typhoid.		Diph.		Aureus	
		tests	results	tests	results	tests	results
400	v	2	g	.....	.....	.....	.....
350	w	.....	.....	.....	.....	2	g
300	x	.....	.....	.....	.....	1	o
300	y	2	o	.....	.....	.....	.....
300	z	2	o	.....	.....	.....	.....
250	aa	.....	.....	1	o	1	o
250	bb	.....	.....	2	o	2	o

These results demonstrate that 1 c.c. of formalin to 300 c.c. of air will thoroughly disinfect books in fifteen minutes, while with an exposure of one hour no greater amount of air can be permitted without vitiating the result. If the exposure be extended to twenty-four hours, disinfection failed to be obtained with 375 c.c. of air to 1 c.c. of formalin. In a few cases, experiments *g*, *n*, *o*, *p*, positive results were obtained where a larger amount of air was used, yet sterilization is not sure with more than 300 c.c. of air to 1 c.c. of formalin.

Experiments were also conducted to determine the detrimental action if any on instrument and rubber. No injury was perceptible to instruments nor to any form of rubber after an exposure of twenty-four hours in air saturated with vapor of formalin. These articles were not, however, subjected to repeated exposures for a large number of times.

The white deposit spoken of by some authors as an objectable product, appeared only to a slight degree on the glass plate where the dishes containing the formalin stood, and it did not show in the least on the books, rubber, instruments, nor on the interior of the bell-jars.

CONCLUSIONS.

1. Books can be disinfected in a closed space, simply by vapor of commercial formalin by using 1 c.c. of formalin to 300 c.c. or less of air.

2. The vapor of formalin is rapid in its disinfectant action. The effect produced in the first fifteen minutes is practically equivalent to that observed after twenty-four hours.

3. An increase in the amount of air to each c.c. of formalin is not counterbalanced by an increase in the length of time of exposure.

4. In case the disinfection has been incomplete, the vitality of the organisms has been so weakened that they survive only if transferred in a few hours to media, suitable for their development.

5. The use of vapor of formalin is not detrimental as far as observed in any manner to the books, nor is it objectionable to the operator beyond a temporary irritation of the nose and eyes, somewhat similar to that produced by ammonia.

CLINICAL MEMORANDA.

A REPORT OF TWO UNUSUAL SURGICAL CASES.[1]

By J. C. ROCKAFELLOW, M.D.,
OF PHILADELPHIA;
RESIDENT PHYSICIAN OF THE GERMAN HOSPITAL.

CASE I.—Dislocation of the radius forward and ulna backward at the elbow-joint.

H. N., aged fifty-three, male, was working on a scaffold which gave way, causing him to fall about sixteen feet. He struck upon the palm of the left hand, the arm being slightly flexed. He was brought immediately to the hospital, where he was seen about twenty minutes after the accident occurred. The patient had intense pain in the elbow-joint, which was somewhat swollen. The arm was slightly flexed and pronated. The olecranon could be plainly felt posterior to the humerus, the coronoid process occupying the olecranon fossa. The head of the radius was displaced into a position anterior to the humerus at the edge of the coronoid fossa. Any attempt at flexion, extension, or supination of the forearm caused intense pain. No fracture of any bone could be determined.

Reduction was attempted by flexing the forearm upon the arm, using the knee as a fulcrum and at the same time making extension. The bones apparently slipped

[1] I am indebted to Dr. G. G. Ross for the opportunity of reporting these cases, which occurred during his service at the German Hospital Dispensary.

into place, but on examination, the forearm was found to be pronated, and could not be supinated without causing great pain. The ulna occupied the normal position, but the head of the radius still rested on the anterior surface of the humerus. By slightly flexing the forearm and making pressure downward over the head of the radius, the latter slipped into place, making flexion, extension, supination, and pronation quite easy, and accompanied by little pain. The rest of the treatment was that carried out in cases of simple dislocation at the elbow-joint. The patient recovered with a perfectly movable joint.

The infrequency of the above dislocation makes it one of interest. The first cases of posterior dislocation of the ulna and anterior dislocation of the radius at the elbow-joint were reported by Michaux and M. Bulley in 1841, each of these gentlemen reporting one case. The next case reported was by M. Meyer in 1880. These are the only uncomplicated cases recorded (Hamilton). A similar case was reported by Dr. Erskine Mason, but he could not satisfy himself that a fracture of the external condyle of the humerus did not also exist.

Of the four preceding cases, two were not diagnosed until two weeks after the injury was received, and attempts at reduction were not successful, as the head of the radius continued to occupy its normal position.

Case II.—Comminuted fracture of the scapula involving the spine.

J. B., twenty-seven years of age, male, while riding a bicycle over Belgian blocks, caught the front wheel between two sewer plates and was thrown about ten feet. He turned completely over, striking the right scapula on one of the stones. The patient was seen soon after the accident occurred.

On examination, no marked deformity was noted, the pain and swelling were slight, but movements of the affected side were limited and painful. The patient could place the hand of the affected side on the opposite clavicle, but could not place it upon his head, a symptom mentioned by Gross as being present in a similar case. Any attempt to place the arm at right angles with the body caused marked pain. The slight build of the patient favored satisfactory examination.

On passing the fingers along the spine of the scapula, the fracture could be felt extending perpendicularly across it, about two and a half inches from the inner border. By grasping the spine on either side of the fracture, each half could be moved separately, and crepitus was distinct. On examining the outer edge of the scapula, a third fragment was found slightly separated from the outer upper fragment, the line of fracture extending transversely and communicating with the perpendicular fracture. The displacement of the fragment was not marked, but, by grasping it, distinct motion and crepitus were felt.

The dressing employed in this fracture was a firm pad in the posterior part of the axilla, a compress over the scapula, the arm in the Velpeau position, all of which were retained by strips of adhesive plaster. Over this was placed a Velpeau bandage. The displacement after the fracture had united was slight, the inner fragment being displaced upward about one-fifth of an inch. The displacement, together with the callus, could be plainly felt at the seat of fracture. The smaller fragment of the outer half showed no displacement.

The above fracture is quite rare, Hamilton having treated but six cases of fracture of the body of the scapula. Various hospital statistics show that fracture of the body of the scapula occurs once in about every four hundred fractures treated, and as most fractures of the body are due to gunshot injuries (Agnew, Ashhurst, Hamilton, and others), the percentage of cases otherwise injured is very small.

A CASE OF SUPPURATIVE CHOLECYSTITIS, WITH RUPTURE OF THE GALL-BLADDER AND GENERAL PERITONITIS, COMPLICATING TYPHOID FEVER.[1]

By HENRY B. ANDERSON, M.D.,
of Toronto, Can.;
Professor of Pathology, Trinity Medical College; Pathologist to Toronto General Hospital.

John S., aged sixty-seven, builder. Admitted to Toronto General Hospital, 8 P.M., Monday, September 16, 1895. Patient had been well and working at his trade in Detroit until July 6, 1895, when he was taken quite suddenly ill—chills, fever, vomiting, diarrhea, with general abdominal pains. The chills recurred daily for some time. He was treated for malaria and recovered from his illness, returning to work August 1st, although still feeling rather miserable. He remained at work only a few days, when he became worse, although still continuing to go about. He had chills recurring, as a rule, twice daily, headache, fever, diarrhea, vomiting, and a good deal of abdominal pain on the right side, in the hypochondriac region. He was again treated for malaria, taking quinin until cinchonism was produced, with no beneficial result. He stated that he had been examined before the Mississippi Valley Medical Association, then meeting in Detroit, and malaria was diagnosed. No blood examination was made. Several other men working at the same place as the patient were taken with an illness somewhat similar, and two of them died. As he was gradually getting worse, he left Detroit for his home in eastern Ontario, but on reaching Toronto he was feeling so ill that he entered the Toronto General Hospital, under the care of Dr. Davison, by whose kind permission I report the case. As Dr. Davison was out of town at the time, I took charge of the case and examined the patient's blood for malarial parasites a short time after a chill, but no plasmodia were found. Another examination was made next day, before a chill, and the following condition found: Red blood-corpuscles, six million (Thoma-Zeiss). They were regular in shape. No malarial parasites were found. The hemoglobin was slightly reduced (Fleischel's hemometer and Gower's hemoglobinometer). There was, however, a marked leucocytosis apparent without an actual count. The increase was in the polynuclears. This examination excluded the presence of malaria and pointed rather to some acute inflammatory process. The patient's condition at this time was as follows: He was strong and

[1] Read before the Toronto Medical Society, November, 1895.

well-developed physically and mentally. Temperature was ranging from normal to 102°; pulse 86 to 100, soft and low tension; tongue red, slightly tremulous, with a tendency to dryness; respiratory murmur natural; heart-sounds normal. General aspect of patient was indicative of great suffering. Mind was clear. Abdomen on the right side was full, prominent, and tense; on the left side it was comparatively soft and relaxed. Palpation and percussion produced the most intense pain on the right side, all over the hepatic area in front and behind, and extended some distance below. In no case was this tenderness and pain particularly localized in reference to the liver. On account of the great suffering produced, it was impossible to define the area of hepatic dulness. There was no pain or tenderness in the right iliac region. The left side of the abdomen was quite soft and relaxed, pressure producing no pain. No splenic enlargement could be discovered. There was no eruption on the abdomen or elsewhere. Examination of the urine negative. Diazo-reaction was not tried. No history of gall-stones or previous jaundice could be gotten. Probable abscess of the liver, secondary to some intestinal lesion, was diagnosed. The intense pain and the fulness on the right side continued, and a *localized* swelling made its appearance beneath the ribs opposite the ninth costal cartilage, and extended below it. On the fifth day after entering the hospital the intense pain and swelling simultaneously disappeared. The patient experienced great relief, and felt comparatively comfortable. This was soon followed, however, by *general* abdominal pain and tenderness, though not very intense. Temperature rose to 102⅘°, and on following day to 103°, reaching normal each morning. The pulse became more rapid—112 to 128—and weaker. The tongue was dryer, skin moist and clammy, and patient had involuntary evacuations of urine and feces. He grew gradually worse, became comatose, and died September 26th, the eleventh day after entering the hospital.

The necropsy was made two hours, *post mortem:* There was a general acute peritonitis, with a considerable amount of brownish-yellow fluid in the peritoneal cavity, apparently bile-stained. Microscopic examination of the fluid showed many polymorphonuclear leucocytes, large flat mononuclear (endothelial) cells, yellowish (bile) pigment, and some short, slightly curved rods with rounded ends.

The small intestines were bound together with recent inflammatory adhesions. The solitary glands were swollen, and there was ulceration of a few Peyer's patches at the lower end of the ileum. The floors of the ulcers were clean and smooth. Liver, weight 1815 grams, soft and passively congested. The cystic duct was obstructed by a number of small, faceted gall-stones. The mucosa of the gall-bladder presented a number of small, ulcerated patches, the tissue between the ulcers being reddened from congestion. On the right side of the gall-bladder, about 4 cm. from the anterior margin of the liver, one of these ulcers had perforated into the general peritoneal cavity. Externally the seat of perforation was adherent to the liver by recent adhesions, the whole gall-bladder was greatly dilated and its walls thin. Spleen weighed 170 grams. Other cavities and organs presented nothing worthy of special mention.

Cultures on blood-serum and in bouillon were made from the peritoneal fluid and from the interior of the gall-bladder. In both cases pure cultures were obtained of a rod-shaped bacterium, short, with rounded ends, and apparently constricted in the center. In places they were united to form longer threads. In morphology they corresponded to the bacillus coli communis or to the bacillus typhosus. The bouillon culture remained alkaline, and the reaction for indol could not be obtained. Unfortunately, other means of differentiating these organisms were not tried. Both the tests applied, however, went to show that the organism was the typhoid bacillus.

To sum up the case: It seems probable that the illness, from which he suffered during July, was typhoid fever, from which he had not fully recovered when he left his bed, August 1st, and this accounts for his feeling worse on going about. The presence of the calculi in the cystic duct and gall-bladder made this a point of lessened resistance. The autopsy records of the Johns Hopkins Hospital[1] indicate that the bile is particularly rich in typhoid bacilli during an attack of the disease. The ability of the typhoid organism to set up local suppurative inflammation in different organs and tissues of the body has also been abundantly demonstrated by competent observers. An inflammatory process was thus set up in the gall-bladder with swelling of the mucous membrane, and this, together with the calculi, produced complete occlusion of the cystic duct with accumulation of the purulent material mixed with bile in the cavity. Ulceration of the mucous membrane occurred, and the tension becoming very great, the sac ruptured at the seat of one of the ulcers, setting up a general peritonitis. The symptoms in the second attack were thus coincident with, and due entirely to, the condition in the gall-bladder and its consequences.

The delayed healing of the ulcers found *post-mortem* could be accounted for by the complication described. The case, apart from its rarity, presents a few points of special interest. It is another instance added to the many cases already recorded of the power possessed by the typhoid bacillus to set up suppurative processes in parts distant from what is usually regarded as the chief seat of the disease—the intestine—the organism being carried by the blood-stream. In a series of cases recently published by Flexner[2] he has shown that this mode of transmission of the typhoid bacillus does occur, giving rise, in rare cases, to an actual septicemia, or producing lesions in distant parts of the body.

From a clinical standpoint, these facts show us the necessity of continually bearing in mind the power possessed, not only by the typhoid bacillus, but, as has also been shown, by most other pathogenic organisms (streptococci, staphylococci, diplococcus, pneumoniæ, gonococcus, bacillus anthracis, bacillus tuberculosis, etc.) of setting up, not only the local lesion with which they are usually associated, but, under certain conditions, often not well understood, by gaining entrance to the blood-stream,

[1] Flexner, *Journal of Pathology and Bacteriology*, April 1, 1895.
[2] "Johns Hopkins Reports," vol. v., p. 343.

and thus producing *general* infection of the system or local trouble in distant parts. In this manner we may get anomalous forms of disease, differing not only in their clinical pictures, but also in their prognosis and treatment, from the usual type.

This case also shows that the absence of polymorpholeucocytosis can only be of use in diagnosing uncomplicated cases of typhoid, and that in certain instances, as in the present, it may actually mislead, rather than assist in making the diagnosis.

MEDICAL PROGRESS.

Division and Immediate Suture of the Left Vagus Nerve.—(Makins, *Brit. Med. Jour.*, May 16, 1896.) In removing a secondary epithelioma of the neck, the left vagus nerve was divided just above the center of its cervical portion. It was immediately sutured. No results were noticeable other than the paralysis of the muscles supplied by the recurrent laryngeal branch. The quality of the voice improved rapidly however, and two months later it was nearly normal. Laryngoscopic examination showed the left vocal cord to be fixed near the middle line, and in phonation the right cord moved up to it. Apparently, after suture of the nerve, the adductor fibers partially recovered, but not the abductor ones.

The operator admitted that the functional cavity of the vagus in this case might have been lowered by long continued pressure by the tumors. In his opinion, however, the case proved that one vagus can be divided without danger, and that after division, at least a partial restoration of function is possible.

Complete Removal of a Pancreatic Cyst.—Eve in the *Medical and Surgical Reporter*, May 9, 1896, describes a case of pancreatic cyst occurring in a negro boy, and which was apparently traumatic in orgin. While asleep, the patient was struck in the abdomen by a falling box weighing fifty pounds. He was confined to bed for four days with postration and great pain. Six weeks later, he noticed an epigastric enlargement which progressed. Four months from the time of injury, the size of the tumor so alarmed him that he sought surgical relief. Eve diagnosed the tumor as pancreatic cyst, on account of its smooth elasticity and the light brown fluid drawn from it.

At operation the cyst contained about a gallon of fluid, and was attached to the omentum, stomach, transverse colon and meso-colon. It was removed and the patient recovered, although the cyst wall was so firmly attached to the meso-colon that the latter had to be torn away from the gut for about eight inches, in order to remove the cyst. The complete removal of a pancreatic cyst has rarely been attempted.

THERAPEUTIC NOTES.

The Treatment of Diabetes Mellitus with Lime.—In addition to observations on the significance of calcium as related to diabetes mellitus previously recorded (see Medical News, June 22, 1895, p. 708) Grube (*Therapeutische Monatshefte*, 1896, No. 5, p. 258) reports a series of fourteen cases, in the treatment of which he employed various forms of calcium, especially a mixture of calcium carbonate, ninety-five parts, and calcium phosphate, five parts. Three of the cases were of the severe type of the disease in young people, and in these, while the excretion of urine remained unaffected, the subjective condition improved with increase in weight. In the remaining eleven, which were of mild type in elderly persons, while no good effect was observed, no harm resulted.

Infectious Diseases Treated by Artificial Serum.—In an article in *La Presse Médicale*, June 3, 1896, Bosc discusses the merits of intravenous injections of artificial blood serum, in infectious diseases and toxic conditions. The fluid employed contained sodium chlorid 7 grams, and sodium sulphate 8 grams to 1000 grams of distilled water. It was sterilized by boiling, and injected into a vein at a temperature of 38° to 39° C. Before injection about 8 ounces of blood were drawn, and then 2 liters of the serum were injected slowly into a vein, during 15 or 20 minutes.

In cholera patients, the effects were striking. Thus a patient who was pale, cyanotic, rigid, voiceless, with a scarcely perceptible pulse, was transformed before the injection was finished. The cyanosis and clamminess disappeared, and the pulse became of good volume at 105. "It was as if a corpse was coming back to life."

The injections were followed almost invariably by a chill and high fever up to 40° C. (104° F.), often accompanied by vomiting and diarrhea. These symptoms subsided in a few hours, and on the following day there was a decided improvement in the general condition which concluded in a speedy recovery.

This treatment calls to mind the ancient humeral theories of disease, and the efforts of the physicians of that time to get rid of the humors in the blood by blood-letting and purgatives. These means have only a limited action. The treatment by blood-letting and intravenous injection of artificial serum, followed as it is by exudation into the alimentary canal causing vomiting and purging, merits the name which has been given it of lavage of the organism.

Bosc has had no personal experience with this treatment in typhoid fever and septicemia, but from what he knows of the results others have obtained, he looks for great benefit from its use in these diseases.

The Galvanic Current in Lead-Colic.—According to Lagrave and Regnier (*Le Prog. Méd.*, May 23, 1896), not enough importance is attributed to the use of the galvanic current in lead-colic. When the positive pole was applied by means of a broad zinc electrode to the lower dorsal vertebræ and the negative pole in a similar way to the epigastrium, a continuous current of five to ten milliamperes was found to relieve the pain entirely in fifteen to twenty minutes. With a current of forty milliamperes, obstinate constipation from lead-poisoning was overcome, and a free passage of feces obtained in ten minutes in a case which had resisted the action of drugs.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

THE LEGITIMATE TREATMENT OF ALCOHOLICS IN BELLEVUE HOSPITAL.

IN connection with the unfortunate notoriety that has attended the efforts of the Charities Commissioners to establish a nostrum cure for alcoholism, it may be of no little interest to know what was already being done in that Hospital, not only to relieve alcoholics temporarily, but to develop and establish a cure. It has long been known that about one-half of the patients admitted to the insane pavilion of Bellevue were alcoholics. Before a satisfactory diagnosis could be made as to the mental condition, it was, therefore, necessary to sober up these patients. For the past few years a systematic effort has been made by Dr. Austin Flint, who was on duty in the insane pavilion, to formulate some treatment that should be more far-reaching than the long-established use of bromids and other sedatives. Strychnin has become the drug *par excellence* for these cases, and its effect is so striking and so decided in cases of alcoholism that it has come to be regarded as a specific antidote to alcohol-poisoning. Its immediate effects, when given hypodermically, are most satisfactory and surprising. In the form and dose in which it is now administered, it will clear up nearly every case of alcoholism in from twenty-four to forty-eight hours. The formula used by Dr. Flint is as follows:

Nit. Strych.	grs. viii
Acid. Salicylic	grs. iv
Alcohol	℥ i
Water	℥ iii

Make up antiseptically.
℥ xv = $\frac{1}{16}$ of a grain of Strych.
Sig. ℥ 15 hypo. two or three times daily.

In the alcoholic wards proper Dr. Charles L. Dana has instituted similar investigations and has reached conclusions very similar to those of Dr. Flint. In addition to the use of strychnin, however, Dr. Dana endeavors to throw about the secondary treatment of these cases the strong mental suggestion of a "cure." His custom is to select, for the cure treatment, from the convalescents of an acute attack of alcoholism only those persons who have reasonable intelligence, and show real evidence of sincerity in their desire to reform. He does not hesitate to say that the suggestive and moral influences thrown about the "cure" are borrowed from the idea of the Keeley and other alcohol cures of the country. A more extended account of Dr. Dana's method will be found in another column of the NEWS.

MELANOTIC TUMORS.

IN the last number of the *Deutsche Zeitschrift für Chirurgie*, vol. xliii, p. 498, EBERMAN reviews the literature of melanotic tumors. It is now nearly a century since Laennec named and described these growths, and we are almost as much in ignorance of their nature now as then. Formerly many cases of melanotic carcinoma were spoken of, but now almost all of the pigmented tumors receive the name sarcoma. The writer does not infer from this that there has been any change in the character of the tumors, but simply that the microscope has revealed to us that in most cases their structure resembles that of the sarcomata. But that is largely a question of nomenclature. As the melanotic tumors are nearly all of the alveolar type of sarcoma—a tumor which stands in the border-line between sarcoma and carcinoma—having the alveolar arrangement of the latter, while its cellular elements seem to place

it among the sarcomata. Thus, among the thirty cases of which Eberman had personal knowledge, only four were distinct carcinomata—all of them being of the rectum. Two of the sarcomata were also rectal, while two had their origin in the mucous membrane of the jaw, two sprang from lymph glands, and the remaining twenty were all situated in the skin.

Owing doubtless to their marked characteristics, melanotic tumors have often been used for transplantation experiments upon animals. As long ago as 1843, Klencke succeeded in transplanting such a tumor from one horse to another. Others have had similar successes in inoculating one animal with a tumor from another.

A more interesting experiment was performed by Lanz a few years ago. The infusion of bits of melanotic tumors of the skin, brain, liver, and spleen of a man, was injected into the spleen of a guinea-pig. The health of the animal was not at once affected, but he died six weeks later with an accumulation of pigment in almost every part of his body, so that Lanz felt sure there was a new formation of pigment.

Interesting as this experiment is, it is not sufficient to prove that an animal may be inoculated with a malignant tumor from man, and thus far all attempts in this direction have failed. Equally futile have been all efforts to cultivate artificially the germs and parasites which from time to time have been seen (?) by various observers in malignant tumors. So that the etiological value of such germs and parasites is still purely a matter of speculation.

What an eloquent testimony is this to the cost of human knowledge, that the labor of hundreds of painstaking investigators for nearly a century has reached only these few facts concerning the nature and cause of melanotic tumors.

A NEW SPECIALIST IN A NEW SPECIALTY.

The following letter, which for pure naïvete, colossal egotism, and brutal assassination of the "United States language," has never been outdone, is the latest contribution to the "Healing Art Made Easy." The reading of the first paragraph amused us, the second disgusted us, and at the end we were prepared to say with Shelley, "Adieu to egotism; I am sick to death of the name of self."

Dear Sir: Having settled as a physician in Detroit, and it being the custom, in making such an announcement as is appended hereto, to accompany it with a sketch of one's medical study and experience, permit me to say that I took lectures at Jena, Strassburg, Heidelberg, Göttingen, and Halle, and that at the end of the fifth year I received my diploma in medicine and surgery, and graduated from the latter university, where I had been a voluntary assistant of the late Richard von Volkmann. After ten years successful practice in Germany, I came to this country, for which I had conceived a great admiration during a trip to the World's Fair in 1893. Permit me also to announce that I confine my practice strictly to dermatology and surgery, and to consultations in these matters, thus avoiding that somewhat suspicious (in this country) name of specialist (*sic*).

I pay special attention to orthopedy, a science which, in the last few years, has made just as wonderful progress as surgery, as a whole, after the important discovery of Dr. Josef Lister. This progress was due chiefly to Friederich Hessing, who gave to orthopedy a series of apparatus so perfect in their functions that Dr. Albert Hoffa, in the latest addition of his well-known work on orthopedic surgery, recommends the Hessing apparatus for every occasion.

I use the Hessing apparatus exclusively for all my patients. The results obtained by this method of treatment are so favorable, that I can boldly affirm that up to the present time there has been no other kind of treatment that could successfully compete with this one. The early walking around of a patient with a broken leg, so favorably commented on of late, is an easy matter with a Hessing's apparatus.

The manufacture of Hessing's apparatus is a difficult process, and the proper adjustment is attended with even more difficulty. Therefore, it is necessary in nearly every case, to have the patient for at least three weeks at my office-residence.

It was a long time before I found the proper material and the right kind of skilful mechanics; two items exceedingly necessary to produce a good Hessing apparatus. This, together with the wish to speak the United States language fluently enough to converse without difficulty, is the reason I have not come earlier before the medical profession.

Yours very respectfully,

————, M. D.

We are accustomed to a certain amount of breeziness and brusquerie from some of our Western fraternity, and we were not entirely unprepared for this blast, for it is but a few weeks since we were favored with a similar but a more

carefully worded circular-letter from a certain New York specialist; but there is in this simple letter of the former voluntary assistant of the illustrious Volkmann an unreserved expression of sentiment and thoughts, and likewise hopes, without regard to conventional rules, which really aghast us.

A man who confines his practice to dermatology and surgery, and who uses a Hessing apparatus exclusively for all his patients is a genius; but a genius who has a form of neurosis which the unlettered call insanity. Think of the brilliant results that must follow the treatment of a case of acne rosacea in full bloom with a Hessing apparatus!

We congratulate Mr. F. Hessing who has thus had his name associated with Lister, the immortal, and we commiserate Dr. Albert Hoffa, who recommends the apparatus for every occasion.

We appreciate the compulsion, and the modesty, which has made our correspondent hide his light in the western city so long; "to speak the United States language fluently enough to converse without difficulty," is a praisworthy ambition, and it is well worth patient waiting, for its realization. It is most unfortunate, however, that our Teuton confrère who murders it so unfeelingly and barbarously on attempting to write it, did not wait a decade or two longer before he essayed to speak it.

We are not at all convinced that the erstwhile modest Herr doctor, who has conceived such a strange liking for this country of ours, has yet really found the proper material and the right kind of skilful mechanics for the manufacture of this dermatological and surgical necessity which he considers so essential for us to have. In fact, we believe that he has not. They exist, *par excellence*, in that country where he practised with such signal success for ten years, and we hope that he will not delay his return to them. The profession can spare him, and really it is more than likely that surgeons will be content to cure fractures in the old-fashioned way, with complete success, without further instruction.

If we can in any way assist the profession of Detroit in ridding themselves of this specialist our concurrence is at their call.

ECHOES AND NEWS.

The French Surgical Society.—The tenth session of the French Surgical Association will meet at the Paris Faculty of Medicine, on Monday, October 19, 1896, under the presidency of M. Terrier. The two following subjects will be discussed: "Surgical Therapeutics of Club-foot," and "Treatment of Genital Prolapsus."

The American Electro-Therapeutic Association.—The sixth annual meeting of this Society will be held on Tuesday and Wednesday, September 29 and 30, and Thursday, October 1, 1896, in Allston Hall, the Studio Building, on Clarendon street, Boston, Mass. Dr. W. H. White, 222 Marlborough street, Boston. Mass., is the vice-chairman of the committee of arrangements.

Self-Respect More Valuable than Position.—Dr. James G. Kiernan of Chicago, informs us that after an editorial service of nearly ten years upon the *Medical Standard*, he has now severed his connection with that journal, because of the insistence, "by the publishers, upon intruding nostrum advertisements and the conversion of the journal into a 'write-up' organ for nostrums and allied performances."

Swedish Hospital Projected in Brooklyn.—The fact that a Norwegian feels insulted if mistaken for a Swede, is well known. The Swedes of Brooklyn evidently prefer segregation from their old-country neighbors as well; for they deem the Norwegian Hospital in South Brooklyn inappropriate, and have raised nearly $2000 as the nucleus of a building fund for a Swedish hospital. They hope to raise the remaining amount necessary to their purpose by means of a fair. The certificate of incorporation has been filed in the county clerk's office.

American Association of Obstetricians and Gynecologists.—The ninth annual meeting of this Society will be held at the Hotel Jefferson, Richmond, Va., Tuesday, Wednesday, and Thursday, September 22, 23, and 24, 1896. The proprietors of the "Jefferson" offer special rates to the Fellows of the Association, their families and guests, as well as to any physicians who come to attend the meeting. It is confidently expected that the railways will offer transportation at a uniform rate of a fare and a third on the certificate plan to all in attendance.

The Hardin County Protective Association.—In Hardin County, Ky., there has been formed a Life Insurance Examiners' Association. It includes *every physician in the county*, and many others whose "rides" take them into the county. They will meet and discuss the scientific and financial questions that affect the insurance of human lives. They have also resolved that they will insist upon a fee of five dollars for each examination made for the companies. If this plan works well, it will be because the hearts of Hardin County beat as one, and there are no backsliders.

A Sacrifice to the Cause of Science.—Dr. William H. Park, who is superintendent in charge of the Bacteriological Laboratory of the New York City Board of Health,

and who, by his editorial association with the NEWS, has kept its readers posted in regard to the status of bacteriological investigation, is suffering with typhoid fever. Dr. Park had been experimenting for the Health Department with a view of discovering a typhoid antitoxin similar to the diphtheria antitoxin. It is supposed that some of the typhoid germs got on Dr. Park's hands, and were transferred to his food, or drink, and thus swallowed. His condition is considered favorable for recovery.

For the Prevention of Blindness in South Carolina.—The following are the essential features of the law of 1896, in South Carolina, relating to the care of infants having diseases of the eye: "Be it enacted by the General Assembly of the State of South Carolina, That should one or both eyes of an infant become reddened or inflamed at any time after birth, it shall be the duty of the midwife or nurse or person having charge of said infant to report the condition of the eyes at once to the local Board of Health of the city or town in which the parents of the infant reside. Any failure to comply with the provisions of this Act shall be punishable by a fine not to exceed twenty-five dollars, or imprisonment not to exceed one month, or both."

The Red Badge of Healing.—Two hundred years before the Children's Crusade, merchants of Amalfi had obtained permission from the Caliph of Egypt to build a hospital in Jerusalem for poor sick pilgrims. The Hospital of St. John became well known, and rich Crusaders gave money to endow it. Others joined its medical or nursing staff, and, without laying down their crusading badge, fought now a new fight against the ravages of disease and death. . . . The Genevan Convention, in 1863, which provided for the protection of the sick and wounded in time of war, commanded the sympathy and adhesion of every civilized nation. It adopted as its badge, a red cross on white ground—the Swiss colors reversed. And so it comes to pass that it is under the old crusading sign that present-day deeds of mercy are done on the field of battle.

Obituary.—Solon F. Bliss, M.D., of Brooklyn, died July 24th, in his forty-seventh year, from diphtheria, after an illness of ten days. He was an American by birth, and had practised in Brooklyn during nearly the whole period of his professional life. He was a graduate of the Albany Medical College in the year 1874.—Edward B. Stevens, M.D., died July 11th, at his home in Lebanon, O., aged seventy-two years. He was Professor of Materia Medica and Therapeutics in the Miami Medical College from 1865 to 1873, and in the University of Syracuse from 1872 to 1877. For seventeen years he edited the Cincinnati *Lancet and Observer*, now the *Lancet Clinic*, and afterward the *Obstetric Gazette*.—The death of Sir Robert Grove, the inventor of the Grove cell voltaic battery, occurred in London, England, August 2d. He was a lawyer by profession, but being temporarily prevented by ill health from following legal pursuits, he turned his attention to the study of electricity. In addition to the battery, which bears his name, he also invented a gas battery.

Nearly Two Thousand Cases of Smallpox.—In reading the paragraph given below, from the *London Lancet*, let it be remembered that the estimated population of the afflicted city is only 41,000. "At Gloucester the fresh cases of smallpox arising in the week ended July 2d were 18 in number, exceeding the total of the previous week by 5. These raised the grand aggregate of cases in the present epidemic to 1983. Summonses last week occupied the bench at Gloucester with reference to the obstruction of officers of the sanitary authority in their efforts to secure the removal of cases of smallpox to hospital. In one instance the father of three children down with the disease refused to permit of their being taken to the hospital, and he was fined £1 and costs, or fourteen days' imprisonment. The defendant, by his counsel, desired to bring forward evidence to show that the hospital was not properly administered, that beds were occupied by more than one case, and so on. The bench ruled against the defendant in this respect, but it is alleged that this is not the first complaint that has been made as to the way in which, in the past, the smallpox hospital at Gloucester has been administered."

The Fever Hospital of Hamburg.—Hamburg affords everywhere evidence that it has profited by the fearful scourge of cholera from which it suffered in the autumn of 1892. The city authorities have established such methodical supervision of water, milk, butcher meat, and almost every article of food, as may be declared sufficient to preclude the possibility of a similar epidemic in future. In their supervision of infectious disease they now follow a plan almost military in its thoroughness, precision, and systematic rule. In different quarters of the town there are disinfection establishments, where one finds not only the means to disinfect articles brought from dwellings in which infectious disease has appeared, but a staff of officials furnished with all the necessary apparatus for the disinfection of the dwellings themselves, and for the instant removal of patients to hospitals where they may be promptly submitted to treatment. In the Eppendorf Hospital, which is the largest modern hospital in Europe, affording ample accommodation for nearly 2000 patients, one finds almost every appliance that recent science can suggest for the treatmeut of disease. In this hospital there were at one period no fewer than 3000 cholera patients during the cholera epidemic in 1892. Usually, however, only a few of the pavilions of the hospital are devoted to infectious disease. The pavilions are, for the most part, in two floors.—*Sanitary Journal.*

The Date of the Meeting of the Mississippi Valley Medical Association has been changed to September 15, 16, 17, and 18, in order to permit the members and their families to take the opportunity accorded by this change to make a pleasant tour through the Yellowstone Park, so justly celebrated as the Wonderland of America. Prominent resident members of the Association in St. Paul and Minneapolis are formulating plans for the Special Yellowstone Park Excursion Trip, to leave on the evening of September 18th, arriving in Mammoth Hot Springs in the Yellowstone Park about noon on the following Sunday, and devoting the following five days to the wonders of this remarkable region, returning to St. Paul Sunday, September 27th. The cost of the trip, including all ex-

penses west of St. Paul, will be announced in due season, but we are authorized to say that the figure will be a very favorable one, and we simply wish, at this time, to make the preliminary announcement of this most enjoyable feature of the St. Paul meeting, so as to give members the opportunity of making their plans in advance to join the party. It is desirable that there be a party of one hundred or more, in order to obtain the benefit of the special train service in both directions. It is urged that all members who desire to join the party should send their names to Dr. C. A. Wheaton, chairman of the Committee of Arrangements, St. Paul, at as early a date as possible.

Electrolized Salt Water as an Antiseptic.—Dr. Julien Proger, chief surgeon of the Asylum for Deaf and Dumb Children at Asnières, near Paris, and member of the Sanitary Council of the Department of the Seine, for four months has been using electrolized salt water as an antiseptic, and has now laid the results of his experiments before the Académie de Médicine. This fluid is used in England as a disinfectant in the Royal Victoria Hospital at Netley, and as a deodorizer for the main sewers of Ipswich. The inventor, from the first, has claimed for it powerful and harmless antiseptic properties, and several years ago supplied Dr. Carlier of Rouen, and Dr. Chantemesse of Paris, with bottles of it for surgical and medical purposes. The opinion they expressed was very favorable, and quantities of it have been supplied to persons suffering from wounds, sore throat, sore eyes, etc. In his communication to the Académie de Médicine he gives a technical report of his clinical experiments, and then sums them up by saying: "The electrolized saline water is neither caustic nor irritating; it may be applied to the mucous membrane as to the skin; it instantly removes all bad odors; stops all putrescent fermentation; kills microbes more effectually and rapidly than any other antiseptic; cleanses and heals fetid wounds and sores, and hastens healing; it is an ideal antiseptic." Dr. Proger further declares that he has used it with success in a case of incipient diphtheria.

Nomenclature of Diseases.—The new "Nomenclature of Diseases," being the third edition of the Royal College of Physicians, has at length appeared in a book of five hundred pages. In 1892 the Committee of Revision was appointed, and their work now appears after four years as a substantial and useful manual. Of the origination of the book the editor of the *Lancet* gives a brief explanation: "The idea that led, nearly forty years ago, to the projection of a nomenclature of disease which should possess a national, or rather an international, character, originated in the Army Medical Department, through whose representations, supported by other of the Hospitals Committee of the Epidemiological Society, the Royal College of Physicians of London was induced, in the year 1857, to undertake the preparation of a Nomenclature of Diseases, on the understanding that it should be subject to periodical revision. The work was commenced forthwith, but in 1858 the meetings of the committee appointed for the work were suspended for five years in consequence of the passing of the Medical Act, and the alterations thereby necessitated in the constitution of the College. The meetings were, however, resumed in 1863, but it was not till 1869 that the first edition of the Nomenclature was published. Among changes made in the present edition in the classification of diseases we notice the restriction of the term 'anthrax' to the disease previously named splenic fever or wool-sorter's disease, and the relegation of the morbid condition carbuncle, which had been previously confounded with anthrax, to a separate category. The disease formerly termed epidemic rose rash is now termed 'Rubella,' in deference to the opinion of physicians specially skilled in the diseases of children, the old name "rötheln" being still retained as a synonym. Diabetes insipidus (polyuria) and tetanus are now, for the first time, admitted as new names in the division of general diseases. The section on nervous diseases has been entirely recast, and so likewise have those relating to diseases of the digestive, respiratory, and integumentary systems. The section on surgical operations has been rearranged, as has also the section on malformations. The enumeration of tumors and morbid growths has undergone fundamental alteration in order to bring this group into harmony with modern classification. The class 'cysts' has been retained in deference to usage and to the needs of registration, although it necessarily overlaps some other divisions of the nomenclature."

SELECTION.

THE STRYCHNIA CURE OF ALCOHOLISM AND OPIUM HABIT.[1]

BY C. L. DANA, M.D.,
OF NEW YORK.

A CERTAIN proportion of the submerged four thousand who pass yearly through the alcohol wards of Bellevue Hospital distinctly and seriously wish to have a treatment given them which will take away their tendency to periodical sprees. Consequently the use of strychnia and the solanaceæ, with certain adjuvant tonics and moral influences is employed in these cases. The drugs selected for use in this "cure," are those which the experience of ten years in the care of these cases has shown me to be most useful.

Selected patients, after having passed through an attack of acute alcoholism, and are convalescent, are allowed to remain two days and take the "cure." The wards of the Hospital are not large enough to permit of a longer stay. Only persons who have reasonable intelligence and who show real evidence of sincerity are chosen.

The following solutions are used:

I. ℞

Strychnia nitrat., . . .	gr. 1-15
Atropiæ sulph., . . .	gr. 1-300
Aquæ distilled, . . .	m x

M. Sig. inject t. i. d.
1st day injection.

II. ℞

Strychnia nitrat., . . .	gr. 1-20
Atropiæ sulph., . . .	gr. 1-200
Aquæ, ...	℥ x

M. Sig. inject t. i. d.
2d day injection.

[1] From the *Post-Graduate*, July 1896.

III. ℞

Tinct. cinchon. comp.,	m xv
" capsici.,	m ½ to m i.
" solan. carolin.,	m ii.
Vini ferri amari.,	ad ʒ i.

M. Sig. Mistur. stomachic., ʒ i. t. i. d. Shake.

Order: One-half to one glass of milk (hot or peptonized), alternating with hot beef tea or broth, every two hours.

IV. 1st and 2d nights, if needed.

℞

Potas. bromid.,	gr. xxxii.
Chloral hydrat.,	gr. xvi.
Tinct. valerian,	ʒ i.
Aquæ,	ad ℥ iv.

M. Sig. ʒ i dose, repeated once, if needed. Shake. Mistur. sedativ.

The patients are given the injections I and II and "stomachic" III, three times a day, with abundant nourishment, washing out the stomach, if neccssary, to help any catarrhal disturbance.

The patient, during the treatment, is made to understand distinctly that he is taking a "cure" with all that that implies, but no mystery is made of its character or of the means used.

After the second day he is perforce discharged. In most cases his craving is gone, but this generally occurs after a debauch. In fact, the natural history of many cases of periodical alcoholism is that craving ceases after the spree for from one to nine months.

On being discharged, the patient is given

V. ℞

M. Sig. ʒ i t. i. d. in water after meals.

The patient is told to take this and report weekly. After a month he reports monthly, and is kept supplied with the bottle, which he is told to take the minute any craving develops, and report at once.

By the application of this method to alcoholics, we are able to send out many patients with hope in the future, confidence in themselves, and a staff upon which to lean in this weakness. The same treatment, when applied to patients with the morphin habit, has to be given much longer, and sometimes must be modified, by adding bromids, or gradually reducing the morphin. Dr. Brown, the house surgeon, was able in one case to stop immediately the use of morphin taken to the extent of thirty grains a day. The patient did not suffer in the least.

SOCIETY PROCEEDINGS.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

Tenth Annual Meeting, held at Atlantic City, N. J., June 2 and 3, 1896.

FIRST DAY, TUESDAY, JUNE 2d.

THE first order of the session was the address by the President, CLAUDIUS H. MASTIN, M.D., of Mobile, Ala.

A. T. CABOT, M.D., of Boston, read a paper reporting

FIVE CASES OF RUPTURE OF THE URETHRA TREATED BY EXTERNAL URETHROTOMY AND SUTURE.

In all five of his cases the immediate result of the operation was good. In three of them the opportunity was given for examination some years after any dilating instrument had been used. In two of these no stricture was found, and instruments even larger than those that were used immediately after the operation slipped past the point of rupture with perfect ease. In one case, while no interference with urination was noticed, a narrowing of the urethra was found; this narrow point, however, was not of a hard, cicatricial nature, but was so soft and yielding that without the least exercise of force it was rapidly dilated to a good size. The conclusions of the author were as follows: (1) In every case of ruptured urethra, immediate perineal section, with suture of the urethra should be practised. (2) By this procedure not only do we greatly lessen the danger of urine infiltration and abscess, but we also, in a large proportion of cases, may hope to prevent the formation of close intractable strictures. (3) In the early operation, the search for the posterior end of the urethra is much easier than in the later. The hemorrhage from the branch of the artery of the bulb serves as a guide to that end of the canal.

J. WILLIAM WHITE, M.D., of Philadelphia, said that he fully concurred with Dr. Cabot in the general principles laid down in his paper. There was another class of cases, however, in which it was sometimes difficult to decide just what procedure to follow, namely, cases of slight injury, in which there were practically no symptoms excepting a little hemorrhage and perhaps some perineal swelling. In a slight, partial rupture of this character, was the outlook from suturing any better than we could expect from the introduction and retention of a large instrument, and careful urinary antisepsis?

JOHN P. BRYSON, M.D., of St. Louis, said he was entirely in accord with the statement made by Dr. Cabot that an early operation is demanded in a case of traumatic rupture of the urethra. If it could be demonstrated that the lesion in the urethra was transverse or oblique, the indications were to open and suture it. In these cases we often had to deal with a semilunar laceration.

F. R. STURGIS, M.D., of New York, said that when the rupture was slight, the introduction of an instrument to keep the canal patent was often all that was necessary. When, on the contrary, the rupture was extensive, an operation was called for.

ABNER POST, M.D., of Boston, reported a case of ruptured urethra that had recently come under his observation. In that case, the speaker said, the patient would have been better off had an immediate operation been performed and the urethra sutured.

GEORGE CHISMORE, M.D., of San Francisco, coincided with the views of the writer of the paper in every respect, yet he believed that we were a little premature in concluding that a rupture of the urethra, not sutured and left to the healing powers of nature alone, would invariably lead to a particularly intractable form of stricture. He reported a case in which he had an opportunity to examine

the urethra of a patient who had sustained a traumatic rupture of the canal ten years before, and who had had no instrument passed for many years. He found a stricture at the seat of the injury which yielded very readily, admitting, within two weeks, a No. 10 F.

Dr. Bryson said that in the linear form of stricture, which is usually a simple band rising quite sharply from the urethral wall, dilatation will often produce good results and sometimes bring about a radical cure. A longitudinal tear may heal even with the use of a catheter, but in traumatic cases the rupture is usually transverse or oblique.

Dr. Cabot, in closing the discussion, said he agreed with the statement made by Dr. White that it was often difficult to decide whether a case required immediate operation or whether milder measures would suffice. The feeling he had was that if a case which does require early operation is not operated on, it usually does badly. An abscess results together with a cicatricial stricture, which might have been avoided by immediate operation. The actual danger pertaining to such an operation is trivial; it is a much more serious matter if we leave a blood-clot or a tear in the mucous membrane. In case of doubt, therefore, it is well to operate. There are undoubtedly cases where the injury is so slight that we can treat them as indicated by Dr. White, but where there is inability to pass a catheter or a large swelling in the perineum, an operation is necessary. In the case related by Dr. Chismore, the good result was no doubt partly due to the fact that a perineal opening was made, thus preventing urinary infiltration.

JOHN P. BRYSON, M.D., of St. Louis, read the

REPORT OF TWO CASES OF URETHROTOMY WITH TRANSPLANTATION FOR URETHRAL STRICTURES.

The history of the first case was as follows: J. F. was first seen by Dr. Bryson in December, 1891. He had an annular stricture of the urethra, the anterior face of which was situated five and one-half inches from the meatus. The stricture had its origin in a gonorrhea contracted eight years before. It was of the inflammatory variety, resilient, and had repeatedly resisted efforts at dilatation carried beyond No. 14 F. Being convinced that further palliative treatment was useless, the speaker said he opened the canal on December 22, 1891, and disclosed a stricture about one-quarter of an inch in breadth situated at the posterior part of the bulbous sinus, and lined by roughened and inflamed mucous membrane, There was no well-defined margin between the healthy and diseased tissue, the one gradually shading into the other. The membranous portion of the urethra was not much dilated, but was in a state of mild, chronic, purulent inflammation. The urgent request of the patient, who demanded a radical cure of the trouble, which had considerably undermined his health, led Dr. Bryson to disregard the extra risk caused by the posterior urethritis and at once to dissect out the whole of the diseased tissue, going well beyond it on either side, in order to be sure of the mucous membrane. When the dissection was complete, it was seen that the divided ends of the urethra were separated fully three-quarters of an inch, and an attempt to bring them together failed. The base of the wound being composed of spongy and vascular tissue, immediate transplantation of a graft taken from the lining membrane of the prepuce was ventured. This was stitched to the cut ends of the urethra by interrupted catgut sutures. The urethra and bladder were thoroughly irrigated with warm carbolic solution, a catheter passing the full length of the urethra was tied in and the perineal wound propped open with iodoform gauze, loosely placed. On December 24th, the gauze was removed; two days later, the catheter was removed, and on inspection it was found that the graft had taken. The catheter was left out. The patient passed his urine chiefly through the perineal incision. He left the hospital on January 6, 1892, at which time the perineal wound had almost closed. He came under observation again in March, 1894, complaining of a free urethral discharge; after this was cured, a No. 30 F. sound would enter the bladder easily, almost painlessly, and caused no bleeding. On December 26, 1894, the patient reported that he had had no further trouble, and was able to urinate with a full stream. He was again heard from in the fall of 1895, when he wrote that he had remained perfectly well since the operation, urinating with a full stream and at normal intervals, having had no treatment in the interim.

In the second case reported by Dr. Bryson, several attempts at transplantation were made before a successful graft was introduced.

EUGENE FULLER, M.D., of New York, read a paper upon

GOOD RESULTS FOLLOWING URETHRAL RESECTION.

(See current volume of THE MEDICAL NEWS, p. 93.)

DR. WHITE said that in one case of injury to the urethra coming under his observation, a considerable portion of the urethral wall was missing. To fill this gap he used a graft taken from the mucous membrane on the inside of the cheek. He was unable to say whether the graft took successfully or not; the case did well, however, and he was disposed to think that the transplantation was a factor in bringing about the good result.

DR. BRYSON expressed the opinion that in the cases reported by Dr. Fuller—particularly in the last one—the time that had elapsed since the operation was too short to enable him to pronounce them permanently cured. In a case of that character, where an extensive resection was done, it would no doubt take a considerable period of time for the urinary canal to fill up.

DR. CHISMORE regarded the result of grafts within the urethra as very uncertain.

FRANCIS S. WATSON, M.D., of Boston, read a paper entitled

MOVABLE KIDNEY; ITS FREQUENCY; ITS CASUAL RELATION TO CERTAIN DEFINITE SYMPTOMS; THE MEASURE OF RELIEF AFFORDED BY NEPHRORRHAPHY; A NEW METHOD OF APPLYING SUTURES IN THE OPERATION.

He said the pathologist rarely finds movable kidney because, in the first place, he rarely looks for it, and in the second place, as Newman and Kendal Franks have pointed

out, with the body in the dorsal position, the kidney naturally returns to its normal position and is retained there by the solidification of the perinephritic fat after death.

As regards the frequency of this condition, the following figures will prove of interest: Glenard, in 1893, reported that he had seen personally between 1885 and 1893, 537 cases of movable kidney. Lindner, in 1888, asserted that one woman in every five was subject to movable kidney. Edebohls, in 1893, said that he had found 90 cases in a series of 500 women examined.

Upon three symptoms of movable kidney all authorities agree. These are, in their order of frequency: (1) Pain in the loin or abdomen; (2) disturbances of digestion of the character of atonic dyspepsia; (3) neurasthenic or hysterical symptoms. There is one other, which is not often mentioned, but which, when present, is the most characteristic of all, namely, the sickening pain, accompanied by a sense of nausea and faintness, which occurs when the kidney is grasped between the hands or the fingers and thumb. It is just as characteristic, so far as one may judge from the description of patients, as is the peculiar sensation which men feel when the testicle is squeezed. Dr. Watson's method of suturing the kidney in the loin, is as follows: After exposing the kidney by the usual lumbar incision, the fatty capsule covering the posterior surface of the organ is excised and its cut edges are stitched a little distance from the margins of the wound. Two stout chromicized catgut sutures are then passed through two-thirds of the entire length of the kidney, parallel to each other, and through the parenchyma of the organ, at a distance of half an inch from each other. They enter the kidney a little above its lower end and emerge a little below its upper end. Either end of the suture is then passed through the edge of the muscular layer of the wound. Two other sutures are then passed in a horizontal direction through the substance of the kidney, one above and the other below the points of entrance and of issue of the two first sutures, and their ends are also passed through the muscular borders of the lumbar wound. The fibrous capsule is then split throughout nearly the entire extent of the posterior surface of the organ, and reflected, to a very slight extent, toward either side, thus denuding the posterior border of the kidney to the breadth of the little finger. Instead of one end being tied to the opposite end of the same suture, the end of one long suture is tied to the end of the other above, and the same is done below at the points where they pass parallel to each other through the muscular layer. The same is done with the cross-sutures. In this way the danger of the stitches tearing out is avoided. The kidney is drawn firmly into its place and maintained there by the sutures, being suspended as in a hammock.

Dr. Chismore said he had one undoubted case of floating kidney under his observation at present where the condition was discovered by accident; as it had given rise to no marked symptoms, nothing had been done regarding it.

Dr. Cabot said he had operated on quite a number of cases of movable kidney which had given rise to symptoms in different degrees. In some cases the condition gives rise to nervous symptoms, in others to digestive disturbances and in a third class it causes kidney colic. In the digestive, and still more in the latter class of cases, the most favorable results were obtained by operative interference. In his later operations he has adopted the method originated by Guyon, which seems to work very well.

Dr. White said he was quite well satisfied that movable kidney existed far more frequently than many suppose; he was equally well satisfied that too many movable kidneys were being found and operated on to-day. He had never seen a death result from the operation and he had never failed to get at least temporary relief. The diagnosis usually rests between movable kidney and tumor of the gall-bladder, or some other intra-abdominal condition. One of the symptoms to aid us in making a diagnosis of movable kidney is the variation in the quantity of urine passed, due to torsion of the ureter; we may get a history of diminution in the amount passed, followed by a sudden increase and a relief of the symptoms. The symptom mentioned in most of the text-books, namely, percussion over the loin, he regarded of very little importance. The speaker expressed the opinion that most of the symptoms accompanying movable kidney were directly due to the condition itself, and were not of a hysterical character. The traction on the duodenum would account for the gastric phenomena; the obstruction to the outflow of urine would account for the renal symptoms, and the traction on the nerves would account for the nervous manifestations,

Dr. Bryson said that an important reason for operating in these cases was the danger of suppurative lesions. In four cases where he opened the kidney for the purpose of draining a suppurating pelvis, he found the organ much lower down than it should have been. He agreed perfectly with Dr. Watson regarding the characteristic pain produced by compressing the kidney. As regards the proper location of the organ, he had obtained the best results by fixing it in a position where the ureter was neither stretched, nor sufficientiy relaxed to become kinked.

Abner Post, M.D., of Boston, read a paper entitled

POST-CONCEPTIONAL SYPHILIS.

He stated that regarding the possibility of intrauterine infection of syphilis two opinions prevail, one party affirming and another denying its existence, while a third party may be said to consist of those who admit its possibility up to a certain period of pregnancy, and deny its possibility after a date, which is set at various periods by different writers. Those who deny the possibility of such transmission rest their belief upon the well-known relationship between mother and fetus, which does not permit the direct interchange of blood-corpuscles, and upon the probable fact that the contagium of syphilis is carried only by the blood-corpuscles and not by the serum, so that, theoretically, the transmission of the disease through the placenta is impossible. The problem of infection of the fetus during intrauterine life simplifies itself into the question whether pathogenic microbes may be transferred from the mother to the fetus or not. So far as analogy is concerned, different conclusions have been reached by different investigators. The latest opinion on this

subject is to the effect that the microbes of pneumonia and typhoid fever and also the bacterium coli commune pass the placenta and attack the fetus in utero. We are justified in saying that the microbes of certain diseases pass the placenta to infect the fetus, and hence we may infer that intrauterine infection is not impossible in syphilis. To establish the fact that the mother has acquired syphilis during pregnancy and transmitted it to her fetus, Taylor, in the recent addition of his work, lays down a series of propositions which must be proven before the fact of such transmission can be accepted: (1) It must be shown that the father was free from syphilis at the time of conception. (2) The infection of the mother during pregnancy, and her freedom from the disease previously, must be proven beyond doubt. (3) The child must have unmistakable lesions acquired before birth. Dr. Post then reported a case in which the following facts were observed by himself and another physician: The previous good health of the mother was known; the primary sore was seen on the mother during the seventh month of her pregnancy; the secondary eruption occurred at about the average time, and was in full bloom at the time of delivery, two months later; the child was born apparently healthy, or at least without skin-lesions, but a perfectly characteristic eruption, with accompanying snuffles, showed itself at the end of a week; the father accused his wife of having given him the disease when she first showed her local lesions, but afterward confessed that he had acquired the disease outside of marital relations and transmitted it to his wife. The only point where the evidence is assailable is the failure to examine the father as to the truth of his story. Dr. Post reported three other cases where syphilis of the child was thought to be due to inoculation of the mother during the course of her pregnancy, in each case by the father, who had acquired the disease after conception had taken place.

R. W. TAYLOR, M.D., of New York, said that Dr. Post, in his paper, assumed that syphilis was a bacterial disease, and while analogous evidence strongly pointed to such an etiology, yet true scientific evidence to that effect was lacking. The placenta, as a rule, is a good filter, preventing the transmission of the red blood-corpuscles, which seem to be the vehicles of the disease, but if this is so, why have the microbes of syphilis not been found in them? Women who are infected with syphilis during the first few weeks of pregnancy, usually give birth, toward the end of the fourth or fifth months, or perhaps later, to a macerated fetus. When the infection occurs after the fourth or fifth month, they may give birth to either a macerated fetus or a puny, miserable child, which, at birth, shows no evidence of the disease. Admitting that syphilis is due to a microbe which resides in the red blood-corpuscles, and is prevented from coming in contact with the fetus by the placenta, there is nothing to prevent the constant interchange of serum between mother and fetus, and this carries with it the toxins of the disease. In the case reported by Dr. Post, it was a matter of regret that he did not give the father a thorough examination to prove the truth of his statements. Assuming that the father's story was true, and that this was a reliable case of post-conceptional syphilis, it was probably to be attributed to the fact that the placenta of that mother was not competent, that in the utero-placental circulation, owing to a rupture or thrombosis, or some other lesion, there was an interchange of red blood-corpuscles and true syphilitic infection of the fetus.

P. A. MORROW, M.D., of New York, said he had always accepted the theory that syphilis of the mother, acquired after conception, may be communicated to the fetus, and also that the disease may be communicated to the mother by a syphilitic fetus. He had observed a number of cases where the wife was inoculated during pregnancy by a syphilitic husband who had contracted the disease after procreation, resulting in an offspring with unmistakable evidences of syphilis. The theory that the placenta acts as an absolute filter, preventing contact of the syphilitic virus with the fetus, did not, in his opinion, rest on sufficient evidence. He believed that almost all authorities at the present day recognized that the mother may receive infection from a syphilitic fetus, and that the mother, healthy at the date of conception, may afterward contract syphilis and communicate it to her child in utero.

DR. WHITE said there can be no doubt that the placenta acts as a filter. This has been shown experimentally in animals. The speaker expressed the opinion that while the fetus may be influenced by the toxins of syphilis, even to the point of death, he did not credit the theory that syphilitic manifestations in such a child after birth were due to the toxins alone, the placenta having acted as a competent barrier against the invasions of the bacteria themselves. One reason which may account for the rarity of post-conceptional syphilis, probably is that the child, under these circumstances, must undergo a species of vaccination.

DR. STURGIS said it was by no means certain that a bacterium is the etiological factor of syphilis, nor had he ever been able to accept the theory that the placenta acts in the capacity of a filter. It was well known that certain diseases can be transmitted by the mother to the child in utero, which compels us to admit that if the placenta does act as a filter, it is a pretty poor filter after all. Cases of syphilis had been reported where the mother was infected as late as the eighth month, and he expressed the opinion that many similar cases escaped notice for the simple reason that it is exceedingly difficult to get an accurate history of such cases. In a pregnant woman, the primary lesion is apt to escape notice, or may be attributed to some irritation.

DR. POST, in closing the discussion, said that to make a plea for closer observation in these cases was one of the chief objects of his paper.

J. P. TUTTLE, M.D., of New York, reported

TWO CASES OF URETHRAL CHANCRE WITH UNUSUAL SECONDARY SYMPTOMS.

In the first case, the chancre was situated within the urethra about three-quarters of an inch back from the meatus. About ten days after its appearance, the patient complained of general malaise, his temperature rose to 104° F., and he developed an eruption almost typical of

measles, except that it was largely confined to the trunk and upper extremities, and had the copper-colored tinge suggestive of syphilis. There was no bronchial irritation. Later, distinct mucous patches appeared on both tonsils. The eruption lasted about two weeks. The patient improved under specific treatment. The second case reported was one of urethral chancre, followed by muscular pains, which were worse at night, and were so severe in character that hypodermic injections of morphin were necessary to allay them. This patient also developed an endocarditis, and subsequently a meningitis, from the effects of which he had not yet recovered. Dr. Tuttle said he was still in doubt as to whether the muscular pains and the cardiac and nervous symptoms were specific in origin, or due to rheumatism or some other constitutional diathesis.

John A. Fordyce, M.D., of New York, read a paper entitled

CLINICAL AND PATHOLOGICAL NOTES ON SYPHILIS.

The first portion of the paper was devoted to a description of the pathological appearance of the lesions met with in the various stages of syphilis. The second portion was devoted to the subject of *myositis syphilitica*. The author stated that while involvement of the muscles in syphilis is by no means of frequent occurrence, it is met with both in the early and late stages of the disease. Before or during the outbreak of the early eruption, general or localized muscular pains not infrequently occur which simulate rheumatism and interfere to some extent with the movements of the implicated muscles. These muscular pains are transient in duration, produce, as a rule, no evident change in the parts, and readily disappear under specific treatment. In the late secondary or tertiary periods of the disease a diffuse or gummatous myositis has been observed. Both of these forms impair the functional activity of the muscles and lead at times to permanent changes in the parts. The disease seems to show a predilection for certain muscles or groups of muscles, among which may be mentioned the biceps, the flexors of the forearms, the masseter, the sphincter and externus, the deltoid, and the sternocleidomastoid. In diffuse syphilitic myositis the first changes seem to take place in the blood-vessels of the interfibrilary connective tissue, the muscular substance being affected secondarily. In neglected cases, or where the cause is not recognized, atrophy may occur and a complete cure become impossible. A correct diagnosis and early treatment insures, as a rule, a good prognosis. The speaker then reported a case of syphilitic myositis occurring in the second stage of the disease; in this case the left sternocleidomastoid was affected. The case occurred in the practice of Dr. P. A. Morrow. Another case was reported illustrating the gummatous type of the disease. In that instance also the sternocleidomastoid muscle was involved. In the concluding portion of his paper, Dr. Fordyce reported in detail an interesting case of brain syphilis. Numerous photographs were exhibited in connection with the various subjects discussed in the paper.

Dr. Taylor said that Dr. Fordyce's work in the pathology of syphilitic lesions, as well as his description of the muscular lesions of syphilis, were entirely in accord with our classical knowledge. The clinical cases reported, particularly that of brain syphilis, were very interesting.

Dr. Post said that during the past year he had seen two or three cases of myositis which clinically might be syphilitic, but which occurred in individuals in whom no history of that disease was obtainable, nor were there any other symptoms pointing to it.

George E. Brewer, M.D., and Pearce Bailey, M.D., of New York, presented the

CLINICAL AND PATHOLOGICAL REPORT OF A CASE OF CEREBRAL SYPHILIS.

F. M. A., aged twenty-five, single. Was first seen in the autumn of 1892. Family history negative. Aside from a moderate amount of neurasthenia the patient had alwas enjoyed fair health. At the time of his first visit he complained of headache, sore throat, deafness, ringing in the ears, and general malaise. Upon examination, an indurated ulcer was found on the penis, with enlarged inguinal, cervical, and epitrochlear glands. There was a well-marked macular syphilide on the chest and abdomen; mucous patches were found on the tongue, lips, and tonsils; there was an otitis media on the left side. Under the use of inunctions, which were continued for several months, followed by the protoiodid of mercury, given internally, rapid improvement in all his symptoms took place, and he returned to his home in the South, where for a period of eighteen or twenty months he was under the care of another physician, who prescribed mixed treatment. During all this period he remained well and was free from noticeable manifestations of the disease. About three and a half years after the date of the original infection he again came under observation, complaining of severe occipital headache, radiating down the back, and accompanied by occasional attacks of vertigo. The pain was more severe at night, and was sometimes associated with nausea, vomiting, and extreme restlessness. Examination at this time revealed slight enlargement of the left pupil, incipient double optic neuritis, and a marked increase in all reflexes; no paralysis; no foot clonus; no changes in sensation; no loss of sphincter control, Under mercurial inunctions and increasing doses of potassium iodid, rapid improvement in all his symptoms occurred. On April 20th, after five days of freedom from headache and all abnormal head symptoms, he was suddenly seized with loss of consciousness and an epileptiform convulsion, involving all the extremities. Ten hours later another slight convulsion occurred. He became restless, excited, and mildly maniacal. The temperature, which up to the present time had been normal, now rose gradually to 104° F. The pulse remained below 100 and was firm and regular. There was no embarrassment of respiration. In spite of vigorous antisyphilitic treatment, he gradually sank into a comatose condition, and died on May 6th, 1896.

At the autopsy, made a few hours after death, the pia appeared normal over the convolutions, but at the base of the brain it was opaque and thickened. At the superior termination of the basilar artery, and enclosed by thickened meshes of the pia, was a round tumor, seventy-five milli-

meters in diameter. This tumor lay between the third nerves, slightly indenting the pons, on the under surface of which it pressed. It was formed by an aneurismal dilatation of the basilar artery, the walls of which were partially destroyed. The basilar artery was filled with a red thrombus throughout its entire extent, and the upper portion of the vertebrals and part of the posterior communicating arteries were likewise occluded. There was no softening. Microscopical examination showed an endarteritis of some of the large arteries at the base of the brain and the aneurismal dilatation of the basilar artery.

Dr. Bailey, in discussing the paper, referred to the rarity of cases of acute cerebral syphilis, which afforded an opportunity for pathological investigation. The pathology of cerebral syphilis showed that the blood-vessels were the most common seat of the lesions in fatal cases. It was not definitely known in which coat of the vessel the morbid process begins, but the intima showed the most marked changes. It was impossible to distinguish, histologically, between specific endarteritis and endarteritis due to atheroma. The prognosis of acute cerebral syphilis depends upon the predominating anatomical character of the inflammation.

REVIEWS.

Burdett's Hospitals and Charities; 1896. Being the Year-book of Philanthropy. Seventh year. London: The Scientific Press; pp. 856.

The author of this volume is well known by his famous work on the "Hospitals and Asylums of the World," the materials for which was collected during a personal visitation of the hospitals of all countries. This "Year-book" is the seventh of the series and its statistical matter is for the year 1894. The author states that this book deals each year with institutions which expend twenty to twenty-five millions. It contains, in convenient form for study or reference, the revenue, cost, and management of the charities of all English-speaking nations. An examination of its pages shows that it makes a just claim to be a reliable guide to British, American, and Colonial hospitals and asylums, medical schools and colleges, religious and benevolent institutions, dispensaries, nursing and convalescent institutions.

Nearly one-third of the volume is devoted to a discussion of the many current and vital questions connected with public charities. In as many chapters we find the subjects to be "Events and Progress in 1895:" "The Misuse of Hospitals;" "A Central Hospital Board for London;" "The Cost of Hospital Management and In-and-Out Patients' Maintenance;" "Some General Charities, including Home and Foreign Missions;" "Orphanages, Homes, and Refuges;" "Convalescent Homes and Institutions for the Blind, and the Deaf and Dumb:" "Hospital Finance;" "The Hospital Commissariat;" "The Construction of Hospital," etc.

These chapters are full of information, and suggestions which ought to have a wide diffusion among those engaged in the supervision of charities of every variety. A study of these chapters would be of special value to legislators, and to the charitable public, on whose donations institutions of this kind depend for support. The author condemns unsparingly the real vices of administration of charities, while he generously defends them from the too common charge of great recklessness of expenditure of funds contributed for their support.

Borderland Studies: Miscellaneous addresses and essays pertaining to medicine and the medical profession, and their relations to general science and thought. By George M. Gould, A.M., M.D. Philadelphia: P. Blakiston, Son & Co. Pp. 384.

The author of these essays is no stranger to these columns; indeed, not a few of the essays first saw the light in the News during his period of service as editor. Most noticeable is their deeply thoughtful and argumentative character, often their somberness, sometimes with an undertone of sadness, not infrequently an appealing quality, whether the author wills it or no. So far as we can comprehend the author's faith, it is nor to us a cheerful one. Schelling and Schopenhauer are not cheerful masters. Life, as a divinity, a basis of faith and hope, is often appealed to; but whether as supreme, in a pantheon, remains to us obscure, both as to concept and expression.

That the fact of immortality should be questioned seems to the author irrational, if not immoral; but immortality of what, and leading to what experience? Is it the immortality of mere atoms, or of something else? The author does not appear to know; and if others have clearer vision in such matters, or, at least, conceptions which are more satisfying to them and quite as logical, from their premises, wherein is the utility or the humanity in arguing them away and replacing them not at all, or with nothing which is substantial to those who are most concerned.

We have given the metaphysical elements of these essays this prominence, for they are really the most noteworthy, and the author's bias in this direction is all too evident, notwithstanding his consignment, in his first essay (p. 23) of all metaphysics, theology, and philosophy to the uttermost limbo when compared with the results and advantages of modern science.

In the essays concerning language, especially medical terminology, we can scarcely agree with him as to his orthography or his etymology. As a purist, he surely should not approve of hybrid and incorrect terms merely because usage has sanctioned them; and as a purist, again, his choice of terms (*e.g.*, baddish, bunglesome, pernicketty) is frequently quite as objectionable as those which he dislikes.

Notwithstanding the opposition which is aroused, we are willing to credit our author with much that pertains to the sincere reformer, much that implies struggle and aspiration for higher and better things, politically, morally, and socially. His love of nature, animate and inanimate, hatred of shams, desire for that which is unconventional, appreciation of that which is beautiful in nature and in art, all declare what the man is, find expression often in terms of decided beauty, and will meet with the responsive chord in many who will disagree most radically with his theological and metaphysical speculations.

ORIGINAL ARTICLES.

FIBRINOUS BRONCHITIS, WITH REPORT OF AN ACUTE CASE.[1]

BY JOHN WINTERS BRANNAN, M.D.,
OF NEW YORK;
ATTENDING PHYSICIAN TO BELLEVUE AND WILLARD PARKER HOSPITALS.

THE subject of fibrinous bronchitis has never been discussed by this Association, though one of our members, Dr. W. C. Glasgow,[2] published an exhaustive study of the affection some fifteen years ago. The disease is extremely rare, particularly in the acute form.

The following case came under my observation in July, 1895:

Mrs. G., aged about forty-five and in excellent physical condition, had been under my care for some ten days for a Colles' fracture of the right arm. Her family record was negative, with the exception of a history of gout or rheumatism on the maternal side. She herself was of an excitable nervous temperament, and had had symptoms suggesting gouty tendencies. On the 29th of June, I changed and reapplied the splints to her arm, and left her in apparently perfect health. Two days later, on the morning of July 1st, I was sent for in haste, and found her in considerable distress. She stated that she had gone to bed the night before as usual, feeling perfectly well. During the night she was awakened by a sense of oppression in the chest and great difficulty in breathing. Toward morning she was taken with paroxysms of coughing, which finally resulted in the expectoration of clumps of a grayish-white substance, which was floating in a glass of water on my arrival. The expectorated masses, when shaken up a little in the water, proved to be a rather firm, tough membrane, resembling that found in diphtheria, but branching and twig-like in form. It had evidently come from the medium-sized bronchi of the lungs. There was no involvement of the upper respiratory passages. The dyspnea had been greatly relieved by the expulsion of the bronchial casts. There was but little fever, the temperature being about 100°, the pulse was 96, the respiration somewhat quickened by the patient's nervous apprehension.

Physical examination was almost wholly negative in its results. The percussion note was resonant throughout the chest, the breath sounds were somewhat diminished, but there were no râles or other evidences of an inflammatory process in the lungs. I prescribed a simple expectorant mixture of iodid of potassium and muriate of ammonia, with codein to quiet the mental agitation of the patient. On the next day a few scattered moist râles were heard in the lungs. Casts were expectorated at intervals for two or three days, but otherwise the case pursued the course of a mild catarrhal bronchitis, and the patient was well in a week.

On questioning the patient as to her past history, I learned that she had had one similar attack, but much more severe, some ten years before, which had lasted two weeks. At that time (the patient was then under the care of the late Dr. A. L. Loomis), as on this occasion, no exciting cause for the onset of the disease could be determined. There was one other fact of interest in the history of this patient, which may perhaps throw some light upon the etiology of fibrinous bronchitis. She said that several times in her life she had had circumscribed swellings upon different parts of the body, but especially upon the arms and hands. The swellings came on suddenly, sometimes after she had by chance plunged her hands into very cold water, but at other times without evident cause, unless perhaps indigestion or some mental disturbance. The description of the affection corresponded with that of angioneurotic edema. According to Dana,[1] there is reason to believe that neurotic edema may sometimes attack the stomach, or even the lungs, though he considers the latter unlikely, as the vasomotor innervation of the pulmonary blood-vessels is very stable. It is known, however, to attack the larynx and throat, and it is within the range of possibility that fibrinous bronchitis is an angioneurosis of the bronchi, resulting in a fibrous exudate instead of the serous transudation of neurotic edema.

Fibrinous bronchitis has been the subject of several elaborate reviews during the past thirty years, notably those by Lebert,[2] Riegel,[3] Glasgow,[4] West,[5] and more recently Beschorner.[6] I shall not, therefore, deal with the disease at length, but shall simply touch briefly upon some of the most striking features.

The etiology and pathology of fibrinous bron-

chitis are most obscure. Modern investigations have added little to our knowledge of the affection, beyond establishing the nature of the exudate in the bronchi. Until the middle of the present century, the expectorated masses were variously described as pulmonary blood-vessels, fleshy polypi, coagulated blood, inspissated mucus, lymphatic concretions, or cast-off bronchial mucous membrane. Remak,[1] in 1845, was the first to insist upon the fibrinous character of the membrane, and he gave to the disease the name of "fibrinous bronchitis." Beschorner, in his recent article, states that in two cases observed by him the bronchial casts were composed of mucus. All other modern writers agree that the exudate is made up mainly of fibrin, containing in varying proportions epithelial cells, leucocytes, fatty matter, air bubbles, and granular detritus.

Some acute cases, whose clinical course resembled that of an acute infection, were thought to be diphtheria with unusual localization of the exudate. The membrane in these cases, however, failed to show the Loeffler bacillus in any instance, and inoculation of animals also gave negative results. Other microörganisms have been reported by two observers. Picchini[2] found three varieties of cocci in the expectoration of three laborers who were affected simultaneously with the disease. He apparently made no cultivation of the microörganisms, but inoculation of the trachea of animals produced an affection resembling fibrinous bronchitis in the human subject. Sokolowski,[3] in a recent paper, describes an acute case, characterized by high fever of two weeks' duration, in which the staphylococcus aureus and the staphylococcus albus were found in the expectoration. He succeeded also in reproducing these microörganisms in various culture media. Sokolowski is therefore of the opinion that acute fibrinous bronchitis conforms to the type of an infectious disease, and is possibly caused by the staphylococcus aureus and albus. He also believes that chronic fibrinous bronchitis is, etiologically, quite distinct from the acute form of the disease.

Fibrinous bronchitis is observed more frequently in males than in females. It occurs at all ages, but most often between twenty and fifty years of age. A few cases have been reported in early childhood, and one case at the age of seventy-two years. Hayn,[4] in 1842, described the *post-mortem* findings in the case of a newborn infant that seemed perfectly well at birth, but died a half hour later. On autopsy, the bronchi and bronchioles were found filled with a fibrinous exudate.

Among predisposing causes, tuberculosis has been assigned great weight by some authors. Syphilis also has been noted in a few cases. On the other hand, many of the persons attacked had previously been in good health. It is probable that neither tuberculosis nor syphilis has any direct etiological connection with the disease. A family predisposition is occasionally seen, cases having been reported in which several members of the same family have been affected by it. In many instances, fibrinous bronchitis has apparently taken its origin from a catarrh of the bronchi of greater or less duration. Sometimes it has followed exposure to atmospheric changes, as in ordinary bronchitis. In other cases, no such exciting influence could be ascertained. It would seem that some especial individual predisposition must exist in the person attacked, but the nature of this predisposition is, as yet, unknown to us.

Fibrinous bronchitis occurs in both acute and chronic forms. The acute form may begin like a simple bronchitis, or the onset may be marked at once by urgent symptoms, such as chill, high fever, paroxysms of cough, and intense dyspnea. These symptoms may continue for several days, and are not relieved until the fibrinous casts are expelled. In the case of my patient, the expectoration of the casts began within twenty-four hours after the beginning of the attack. The expulsion of the casts is sometimes attended with hemoptysis, which may be profuse. There is usually a decided fall of the temperature, which rises again if the casts reform. Immediate relief follows upon the ejection of the membrane, and in mild cases the patient convalesces rapidly. In severe cases, in which the casts are not expelled, cyanosis supervenes, and the patient dies of asphyxia or exhaustion. In one fatal case, a tracheal cast lodged in the glottis and caused death by suffocation. The duration of the acute cases varies from a few days to two weeks. About one-half of the acute cases terminate fatally, sometimes as early as the third day.

The symptoms in the chronic form of the disease resemble those just described, but are, as a rule, less urgent. The attacks usually follow upon long-continued bronchial catarrh. The disease may last for years, the paroxysms recurring at regular or irregular intervals. The interval may be as long as sixteen years. In one case, attacks occurred daily for seven years, then

[4] Cited by Beschorner, loc. cit., p. 624.

ceased entirely. Physical exploration of the chest during the attack often reveals little that is distinctive. Resonance on percussion is normal. The respiratory murmur is usually more or less suppressed over the region of the occluded bronchi. If one lung only is affected, inspection may show less movement of that side of the chest. Râles may be heard if there be accompanying bronchial catarrh. A flapping or fluttering sound has been described in some cases, when the casts have become loosened in the bronchi. After expulsion of the casts, respiration may be heard in the parts of the lung before impervious to air.

But little remains to be said of the pathology of fibrinous bronchitis, in addition to what has been stated above. On *post-mortem* examination, the bronchi usually present the appearances of ordinary catarrhal bronchitis, and in addition, contain membrane more or less widely distributed. In acute cases, both lungs are involved, as a rule. In chronic cases, the process is generally more circumscribed. The membrane is molded to the shape of the bronchi, and is somewhat firmly attached. The casts are insoluble in water, but are soluble in alkalies, especially in lime water, a fact of therapeutic importance. As already described, they consist of coagulated fibrin, intermingled with cells of various kinds. Two explanations are offered of the mode of origin of the coagula in the bronchi. According to Klebs,[1] the casts are formed from transuded plasma of the blood, combined with an exudate of white blood-cells, which have escaped from the vessels. E. Wagner,[2] on the other hand, believes that the casts owe their origin to a pecular metamorphosis of the epithelium of the bronchial mucous membrane, by which the epithelium forms the cellular elements by endogenous cell production and the fibrinous framework out of the remaining cellular substance. The view of Klebs has, at least, the merit of greater simplicity. He, however, in common with all other writers, fails to explain why the exudative process should be limited strictly to the bronchi, and should recur in certain individuals for years at periodic or irregular intervals.

Diagnosis.—Fibrinous bronchitis can only be diagnosticated with certainty when the characteristic arborescent casts are expectorated. A probable diagnosis may often be made if there be a history of previous expectoration of membrane, and the patient exhibit the symptoms and physical signs already described. The diagnosis is often difficult with young children, who swallow their expectoration. Beschorner suggests that probably some cases of acute, suffocative bronchitis are really fibrinous bronchitis. Six such cases are reported by Legendre[1] and Fauvel,[2] which ran the ordinary course of an acute, intense bronchitis, ending fatally. On autopsy, pseudo-membrane was found in the finer bronchi and bronchioles of both lungs. Even in adults, the real condition may not be appreciated if the case terminates without dislodgement of the casts. Cutler's[3] case is instructive in this respect. He saw his patient for the first time some three hours before her death. She was a woman sixty-five years of age, and gave the history of a slight bronchitis of a few days' duration. Cutler found her sitting up in bed, deeply cyanosed, and in a profuse perspiration. The percussion tone was normal. Fine dry râles were heard over the whole chest, and also coarse tracheal râles. Cutler made a diagnosis of diffuse capillary bronchitis. The result of the autopsy was as follows:

> Pharynx and larynx healthy. Tracheal mucous membrane injected in lower half and slightly thickened. A croupous membrane lay reflected on itself over the entrance of the two primary bronchi. When laid in place, this membrane reached less than half way up the trachea. Downward it extended into the minutest divisions of the bronchi, in many of them forming an almost solid plug. The alveoli contained no solid matter and, except in a few places where there was edema or collapse, they contained air.

The prognosis of fibrinous bronchitis is always doubtful. It should be especially guarded in the acute form, as the disease results fatally in one-half of the cases in adult life and in three-quarters of those in childhood. The prognosis of the chronic form is more favorable as regards life, but very doubtful as to complete restoration of health or freedom from future attacks.

The indications for treatment are fourfold: (1) To favor the loosening and expulsion of the casts from the bronchi; (2) to prevent or diminish their formation; (3) to cure or relieve the bronchial or other complications; (4) to improve the general condition of the patient.

The croupous exudate is soluble in lime water and other alkalies, and many observers have seen apparent benefit from the use of lime water in the form of inhalations and sprays, with the addition of caustic soda. Inhalations of steam are also advised. Breathing into rarified air, and compression of the thorax during expiration may aid the expulsive effort of the bronchi. Emetics are

most valuable, especially apomorphia in hypodermic injection. In one severe case, the application of mustard to the entire chest resulted in prompt relief. Potassium iodid is probably the most useful remedy in all forms of the disease. It increases the bronchial secretion when given during the acute paroxysm, and thus aids in expelling the casts. It also seems to lessen the tendency to a recurrence of the attacks if it is given in full doses and for a long period of time.

The catarrhal bronchitis, which so often accompanies the chronic form of the disease, will require appropriate treatment, as will also other complications or sequelæ, such as tuberculosis, emphysema, or asthma. Stimulants may be needed during the acute attacks, and general tonics may be of service in the intervals to improve the nutrition of the patient. A change of climate is sometimes necessary in this, as in other forms of pulmonary disease.

LINEAR SUPRAMALEOLAR OSTEOTOMY FOR DEFORMITY FOLLOWING FRACTURES OF THE LOWER THIRD OF THE LEG.[1]

BY JAMES KERR, M.D.,
OF WASHINGTON, D. C.

JOINT disability following fracture is of most serious import when affecting the articulations of the lower extremities, owing to their weight-bearing function and because they are associated with pain and a physical incapacity tending to increase as age advances, and not infrequently resulting late in life in complete decrepitude. The causes of this have long been recognized, and perhaps best described in the original monograph by Percival Pott, who, in speaking of the effect of the fracture that goes by his name, says: "The due and proper use and execution of the offices of the joint depend almost entirely on the perpendicular bearing of the tibia on the astragalus."

The disability to which I wish to draw attention is perhaps more marked in the case of this joint than elsewhere, and the fractures that more frequently induce it are Pott's fracture and the oblique fracture of the lower end of the tibia. These effects seem to depend on the alterations of the normal articular relations by which the weight-pressure is thrown off the normal axis and bears unduly on one side of the joint, producing at first a feeling of insecurity, and later, pain and lameness. The extra-articular structures, capsule, ligaments, and tendons are subjected to strain corresponding to the amount of axial deviation. Arbuthenot Lane, in a very important contribution to our knowledge of fractures of the leg, says that physical incapacity (the case of laborers) follows in a proportion of seventy per cent. to eighty per cent. in oblique fractures of the bones of the leg, and cites forty cases collected among hospital patients in support of this statement; and most of us have met with such cases among those who lead laborious lives.

He believed[1] that the average financial depreciation of the laborer, as a machine, after such injury, amounted to nearly seventy per cent. of his original value. This he thought due to alteration in the lines of pressure through the several joints of the lower extremity, resulting from deflection of the lower fragments from their original relationship to the upper. In consequence of this alteration, insecurity and pain were experienced in the joints, especially the ankle and foot, and increased with the age of the individual. Pathologically there was a progressive mechanical arthritis in the joints. Mr. Lane consequently advocated operative measures entailing a minimum of risk to the life or limb of the patient, by which the fragments could be brought into apposition and so retained with perfect accuracy that the skeletal mechanics of the individual remained as perfect after the injury as they were before. He cut down on the fracture of the tibia and exposed the broken ends freely, removing any tissues intervening between the sectional surfaces, bringing these surfaces into accurate apposition, partly by traction on the foot, partly by means of elevators, and partly by means of lion forceps, by which last instrument apposition was continued till holes had been drilled and the bony surfaces brought together immovably and forcibly by the introduction of steel screws. He read notes of three cases which he had operated on in the same week. The results were extremely satisfactory, since the fragments had united perfectly. The paper was supplemented by a brief account of forty cases collected by Mr. F. J. Steward, which fully bore out the truth of Mr. Lane's statements.

If these statements are in accord with the facts, the routine methods of treatment in fractures of the leg call for revision. The mistake arises mostly from treating all fractures of the leg in the same way, without regard to the special pathology of each. The two classes of fractures that I am now dealing with cannot be managed without serious ultimate results to the usefulness of the limb by the methods most generally advised, namely in box splints, plaster-of-Paris, or

[1] Read before the Am. Orthopedic Assoc. at Chicago.

[1] Paper read before the Clinical Society of London, April, 1894.

any method by which the limb is kept in the straight position and foot not adjusted and maintained so as to meet the special indications of either fracture. Fracture of the fibula, with fracture of the internal maleolus or rupture of the internal lateral ligament, require muscular relaxation and inversion of the foot. The oblique fracture of the tibia requires the same regard to muscular tension and eversion of the foot. Special indications to meet such displacements, as backward position of the foot in the former, and forward riding of the upper fragment in the latter, are required, but it will be readily seen how frequently any general routine method must result disastrously.

Fig. 1.

BEFORE. AFTER.

These evil consequences of maltreatment are most often found following Pott's fracture, and are common at any age and to all classes. The characteristic deformity, (the axis of the leg making an angle with the foot, best observed from behind, as Langenbeck has pointed out), the lameness and tarsalgia make a striking clinical picture too frequently met with.

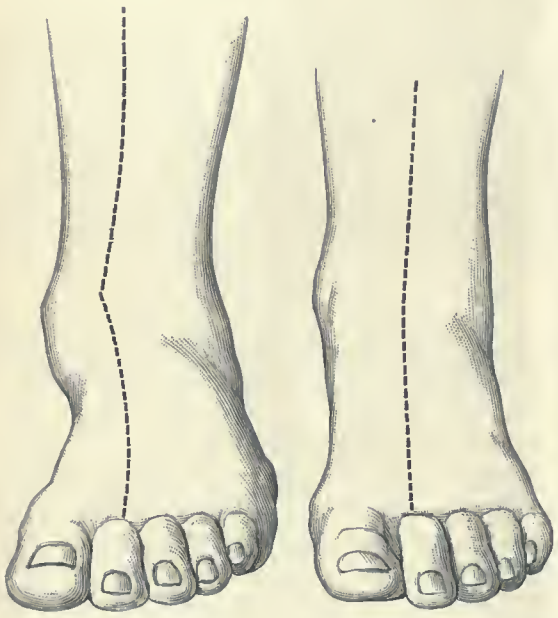
The oblique fracture of the lower third of the tibia is not of so common occurrence, and the deformity and incapacity not so marked. A consideration of its pathology, however, shows that this is due not to correct methods of treatment, so much as to the fact that the axis of the ankle can only be displaced to the limited extent that the upper end of lower fragments can encroach on the interosseous space.

The variety of fracture to which I allude occurs usually at the junction of the lower with the upper two-thirds of the tibia, and is produced by falls on the feet; in fact, it is a fracture by "contre coup," commonly jumping from a moving vehicle, and not infrequently a result of runaway accidents. The line of fracture is from without inward, and from above downward; the lower end of the upper fragment is displaced inward and forward, the upper and lower fragment outward into interosseous space. As a result, the inner maleolus is raised, the articulating surface of the tibia that was at right angles to the axis of the limb is inclined obliquely upward and presents a modified converse to all the conditions that exist in Pott's fracture, the articular relations being altered as to throw the axial weight-line outward, instead of inward, as in Pott's. This fracture of the tibia is usually associated with fracture of fibula high up. Here, as in Pott's, much can be done by proper conception of the pathology and carrying out correct principles of treatment; but where these have not been adopted, the same expedient will apply for correcting its resulting deformity, which I have to suggest for the other, but it must be comparatively rarer that an osteotomy will be demanded for the latter injury. To this particular fracture, Lane's suggestion would apply with peculiar force. There is, perhaps, no other where incapacity is more likely to ensue. It is beyond question that the routine methods of treating all fractures of the leg alike, more especially trusting them to plaster-

of-Paris dressing for long periods, without opportunities for inspection, is responsible for these results. It is also a fact that the ultimate result of a fractured limb is often in strong contrast with the immediate result. Certain changes ensue within the joint—"progressive mechanical arthritis"—as age advances, and which are usually attributed to rheumatism.

The operations hitherto devised for the correction of Pott's deformity include: Refracture by subcutaneous drilling of the fibula and internal maleolus at the site of fracture, subcutaneous osteotomy and open osteotomy at the same locality, and Fenger's supramaleolar osteotomy, by removal of a wedge of the tibia and wiring.

FIG. 3.



FRONT VIEW.

BEFORE. AFTER.

FIG. 4.

REAR VIEW.

BEFORE. AFTER.

The accompanying copies of casts, taken from cases operated on by me, will demonstrate the result of a still simpler, and I submit, equally effective procedure for the correction of this condition. It consists of a simple supramaleolar osteotomy of the tibia alone, similar to, in fact identical with, the Hahn-Langerbach procedure for the correction of valgus. The fibula was not touched, relying on its flexibility, after the tibia was divided, to restore it to its proper relation toward the interosseous space. Examination of the casts also will demonstrate the complete restoration of the normal axial relations between the leg and the foot, which is the sole object of treatment. The broadening of the articulation, which is one of the causes assigned for this disability, is corrected by the bringing inward of the external maleolus as the upper end of the lower fragment is drawn out when the foot is inverted after the tibia has been divided, and I can see a positive objection to the refracture of the internal maleolus, as its abnormal and uncorrected displacement will prevent this broadening of the intermaleolar space. The backward displacement of the foot, which is a common result of Pott's fracture, can be partially restored, as well as the rotary displacement described by Hamilton.

We have, therefore, a simple, safe expedient, within the capacity of anyone capable of accomplishing any ordinary surgical operation according to modern standards, that will only confine the patients a few days to bed, and, with the aid of massage, will give them the use of their corrected limb in from four to eight weeks, according to their age and the degree and length of time of pre-existing disability.

A NOTE ON THE INHIBITORY ACTION OF ACETANILID ON BACTERIAL GROWTH.

BY JAS. J. WALSH, A.M., M.D.,
OF PHILADELPHIA.

ACETANILID has, within these last two or three years, come to be widely used as a dusting powder in surgical practice. The unpleasant clinging odor of iodoform led surgeons to welcome anything that promised to replace it successfully. A number of powders, including various combinations of boric acid, had been used for some time but without much satisfaction, when on purely empirical grounds, acetanilid began to be em-

ployed. It has a number of advantages besides its freedom from odor. It is absolutely cleanly, disappearing completely in the secretions of the wound under ordinary circumstances; it is distinctly analgesic locally, and while it has, like iodoform, the power when used in large quantities, on an absorbing surface, of producing constitutional symptoms, these are not so severe or so dangerous, and more warning is given before the patient is seriously attacked.

Very little laboratory work has been done on acetanilid, and not much of this has been reported, but its use in dispensary practice has constantly increased, until now it has too firm a hold clinically to be displaced by any unfavorable dicta of the bacteriologists.

As a germicide in ordinary cultures of pathogenic or non-pathogenic microörganisms, it seems to be absolutely without effect. It is, of course, only very slightly soluble (1 part in 194 parts of water), so that it would indeed be a powerful germicide if solutions of it in various media prevented microörganisms from growing. Even where considerable quantities of it are present, however, as for instance, where bouillon is thickened by the amount of it present, living organisms may be found in it by culture-methods, even after it has been allowed to stand for weeks.

A series of such observations leads one almost inevitably to the conclusion, that acetanilid is absolutely inefficacious for the ordinary purposes of a dusting powder, and that it owes its vogue to the fad of an hour, initiated by the desire to get rid of the objectionable iodoform. This is the position that a number of practical bacteriologists have taken with regard to it.

There is, however, a series of observations that may be easily made, and that show that in some way, where it is present, it has a very valuable *inhibitory* action on the *growth* of all ordinary microörganisms.

If one half of a gelatin petri-plate, that has been exposed to the air for some time, be covered with a layer of acetanilid (in powder), while the uncovered half will show the development of colonies, some of which will usually cause liquefaction, none will appear on the half beneath the acetanilid. The powder need not be strewn on thickly, a slight uniform layer is enough, and should, of course, be put on *after* the exposure to give the experiment its value.

With water bacteria, the effect is more striking. If from ten to twenty drops of ordinary tap water (especially here in Philadelphia) be added to gelatin within twenty-four hours, from three hundred to three thousand colonies will make their appearance on the surface of a petri-plate poured from it. Many of these will be liquefying varieties. Here again, if one-half of the plate be covered by acetanilid as before, no colonies will develop, and no liquefaction will take place beneath it, while the other half of the plate will show large numbers, and soon be completely liquefied.

The pus microörganisms are inhibited in the same way. The effect of the acetanilid is very clear on the chromogenics. Colonies of *staphylococcus pyogenes aureus* or *citreus* would be so readily visible, if present, even beneath the white powder. Besides, the liquefying effect of these organisms fails, except on the part of the plate uncovered by acetanilid.

Needle cultures made into fresh media from beneath the acetanilid in all these cases, nearly always give positive results in the shape of normal colonies of the various microörganisms present, so that it is only inhibitory, not germicidal properties that are at work.

It is this inhibitory action of acetanilid evidently that has made it popular as a dusting powder, and its clinical value is due to something more than a mere fad. Just why its presence should have this effect seems not easy to tell. Boric acid, which is considered of little value clinically, has the same effect when used in the way described. Here, however, the reaction of the media, which becomes acid beneath the boric-acid powder, has a good deal to do with inhibition, bacteria failing to grow on acid media. Acetanilid, however, affects the reaction of the media slightly, if at all.

It is not that the powder keeps out the air and so prevents all aerobic bacteria from growing, for it was not spread thick enough for that, and inert powders, such as flour, starch, and marble dust, used in the same way, failed to have any effect on the growth, development, and liquefaction of colonies.

As it is only immediately beneath the acetanilid that no growth is seen, the line of demarcation in the media being a sharp one, the necessity for the constant presence of the powder in the wound is clear. Microörganisms are not destroyed and may begin to multiply as soon as the acetanilid disappears. Owing to its limited solubility, the tissue juices remove it very slowly, but the cleanness of wounds dressed with it, shows that it is completely removed after a time, and emphasizes the necessity for comparatively frequent renewal of it, as well as the plentiful use of it, originally.

Very probable its inhibitory action on ordinary air and water organisms, has a good deal to do with its success as an antiseptic powder. For the growth of these in the wound, doubtless, so changes the character of the tissue juices and exudates as to render them less resistant to the invasion of pyogenic germs. And this may be true, even of the most harmless varieties of non-pathogenic organisms. Some recent work in the Royal Laboratory at St. Petersburg (December, 1895), seems to show that it is absolutely true that the pathogeneity of intestinal microörganisms, notably the cholera bacillus, is dependent, to a great extent, on their association in the intestinal tract with such absolutely harmless varieties as the potato bacillus, or the *bacillus cucurbita* (cucumber), or even the ordinary molds, especially *penicillium glaucum*.

CLINICAL MEMORANDUM.

OROLINGUAL PARALYSIS AND SLIGHT MOTOR DISTURBANCE IN WRITING, OF THROMBOTIC ORIGIN; OPERATION; RECOVERY.

BY J. T. ESKRIDGE, M.D.,
AND
EDMUND J. A. ROGERS, M.D.,
OF DENVER, COL.

HISTORY AND EXAMINATION OF THE CASE.

BY DR. ESKRIDGE.

CASES of orolingual paresis, or paralysis in which disturbance of speech-utterance or articulation is the chief symptom, are so rare as to be worthy of careful study. The following is of special interest, both on account of the limited lesion and the marked improvement following excision of the left degenerated cortical area for the lips and tongue.

M. D. E., male, aged fifty, white, single, born in West Virginia, laborer by occupation, living in Colorado eleven years, was admitted into the nervous wards of the Arapahoe County Hospital, December 12, 1895. Mother and one brother died of stomach trouble, father of diarrhea. No nervous or mental diseases in the family, so far as he knows. The patient had most of the diseases incident to childhood. He always indulged in alcohol, but rarely to excess. He enjoyed good health up to his thirty-fifth year, when he suffered from some kidney trouble. He seemed to recover perfectly from this, and was well until 1890, when he contracted a hard chancre. He had a few secondary symptoms, but none of these were well-marked. He considered himself in good health, although he occasionally suffered from headache, until the first of October, 1895. At that time he began to experience severe frontal and occipital headache. The pain was nearly constant, but exacerbations of pain were common during the latter part of the day and early evening. This continued, and about the middle of the month his eyesight began to fail, and by the 28th of October he was compelled to quit work, on account of poor vision. He remained in this condition until November 26th, when, while walking on a street in Denver, he began to feel very dizzy, and staggered against a wall to steady himself and prevent his falling. He was in this position for about an hour, and during this time he began to feel pain in his right hand. A few minutes after he felt the pain in the hand, the hand began to open and shut spasmodically, and about the same time he first experienced difficulty in speaking distinctly. He could think what he wanted to say, but could not articulate, except for a few words, so as to be understood. On trying to use the right hand after the spasmodic action ceased, he found it was nearly paralyzed. The right leg also was weak, and he walked awkwardly. After a few hours he improved somewhat, especially in the use of his leg and arm, but his articulation was very defective. About a week later he noticed that his limbs were getting weaker and his speech, which had improved, was again becoming very indistinct. His headache continued, but it was less severe than before the attack. Just what his condition was between this time and the day of admission to the hospital, I was unable to learn. The first four days of his stay in the hospital he was so stupid and talked so poorly that it was impossible to make a satisfactory examination, and much of the history of his case was gotten little by little, and more by gesture than by speech.

Examination, December 16, 1895: No ataxia in standing with eyes closed. His gait is halting; he walks forward fairly well, even with eyes closed, but in walking backward the right foot is not carried beyond the left. Slight ataxic movements in the right arm, none in the left. All the muscles of the legs fairly strong and about equal in strength in each leg, but those of the right are used awkwardly. Dyn.: R., 22; L., 102. All the movements can be made with the fingers of the right hand, but they are performed slowly and awkwardly. Lower right side of the face is nearly immobile, but the right corner of the mouth is a little more retracted than the left, and the lower right side of the face presents a wasted apperance when compared with the left side. He is unable voluntarily to retract or move the right corner of the mouth. He cannot whistle, as the lips on the right side fail to move at will. He can shut both eyes, but he cannot wink with the right eye. He says that he was formerly able to wink with either eye. The tongue is protruded in the median line, but it deviates to the right after being protruded a short time. Knee-jerks are about normal and not much increased by reinforcing. Plantar reflexes are absent. Tendo-Achillis increased. Cremaster reflexes: R.. absent; L., present. Abdominal reflexes absent. All the deep reflexes of the arms are increased, and nearly the same on each side. Masseters absent. Tactile sense is everywhere present, but it seems a little more acute over the left hand than over the right. Localization and muscular sensations lessened in right hand. Other general sensory phenomena apparently nearly normal, but it is impossible to make a satisfactory examination, on account of his difficulty in speech-utterance and his apparent inability to comprehend just what is wanted. Hearing: Watch, R., ⅙; L., ⅓. The tuning-fork is heard better

in the left ear. Smell and taste present no points of interest. Eyes, R. V. equals $\frac{20}{50}$; fields narrowed; pupil normal in size and responds to light and accommodation; disk a little pale, but presents no marked changes. Central vision is the same in the left eye as it is in the right, but the fields seem normal. Other points about the same as noted in the right eye. All the external ocular muscles of both eyes act well.

Mental Condition: He seems stupid, and says that he cannot think, as his mind becomes blank as soon as he tries to think on any subject.

Speech defect: On thoroughly and sytematically testing his power of speech, no form of sensory aphasia is detected. He understands printed and written words. He reads inaudibly and comprehends what he reads. On his reading aloud, his articulation is so imperfect that it is impossible to understand what he reads, except a simple word occasionally, which by an explosive effort of the lips, he pronounces distinctly enough to be understood, if one is paying close attention. He can write voluntarily, at dictation, and copy, but he had never learned to write well, and he forms the letters very imperfectly with the left hand. He can write a little with the right hand. He copies printing and writing into script. When asked if he understands what he reads, he nods his head, and with an explosive movement of the lips says "Yes." He repeats simple words after another. It is observed that the greater the effort that he makes to pronounce a word, the more nearly he succeeds in pronouncing it distinctly, thus differing from the defect in speech due to a lesion in Broca's convolution. As well as can be determined, he has no difficulty in thinking in speech. He complains of constant headache.

He was placed upon increasing doses of potassium iodid, and a dram of blue ointment by inunction was ordered night and morning. A careful record of the temperature in each axilla was kept, but little deviation from the normal was observed, and the temperature was usually about the same in each axilla. The pulse and respiration showed nothing abnormal. He was examined two or three times each week, and the record shows that he improved, except in his ability to pronounce words. The headache became less, but did not disappear. He looked less haggard and depressed. The right hand and arm gained in strength, and the right leg was used much better.

On January 2, 1896, the following notes were made: "The right arm and leg are much stronger and preserve greater freedom of motion than on December 16, 1895. The reflexes remain about the same. Tactile sense slightly lessened in the right hand, especially on the distal portions of the fingers and on lower right side of the face. Localization and muscular sensations decidedly lessened in right hand. He usually fails to locate the contact of a camel-hair pencil on the right side of the lips and tongue. He still complains of headache and a sensation of exhaustion. His appetite is poor. Mentally he is a little brighter. His power of articulation has improved only very slightly. There is some atrophy of the lower right side of the face. The tongue deviates slightly to the right in protrusion. Vertical and transverse corrugation of the forehead seems about equal on each side. He opens and shuts both eyes at the same time well. He can wink only with the left eye. He is unable to whistle or move the right corner of the mouth. In trying to utter words he makes explosive efforts with his lips, and in pronouncing long words he unduly separates the syllables. In uttering the word 'Columbus' he makes three distinct efforts, so the word sounds thus: 'Cul-um-bus.' 'Truly rural': 'too-lil-loo;' second effort, 'too-e-roo-le.' 'Hurry:' 'urry,' 'flurry,' 'furry.' 'W:' 'dub-you;' second effort, 'dub-ble.' In his letter to-day all the words are spelled and arranged correctly, but the letters are so poorly formed that it is almost impossible to read what he has written, unless one knows what he is trying to write."

The first fifteen days that the patient was in the hospital he steadily, but rather slowly, improved under antisyphilitic treatment. About the first of January he ceased to improve and began to retrograde. His stomach was disordered, he looked pale and haggard, ate little, and was nervous and depressed. His speech-utterance was about as bad as it was on the 12th of December, the day of his admission into the hospital. He was placed on quinin, strychnin, and arsenic, and urged to take nourishing food. Finally his headache became so troublesome that I decided to recommend a surgical operation for its relief.

Diagnosis: The symptoms pointed to a growth or a vascular lesion. There were many points in favor of the presence of a tumor. The headache, impaired vision, and distinct localizing symptoms were certainly in favor of a tumor. The absence of choked disks in a small growth in the anterior portion of the cortical surface of the brain is not uncommon. But the rapid onset of distinct symptoms of a localized brain lesion, while it may occur from a tumor, is much more often due to vascular trouble. The wasting of the muscles of the right lower side of the face indicated an irritative lesion in the cortical face center, but a growth rarely occurs in the motor cortical area of the brain without repeated convulsions. The patient's age and his anemic and depressed condition made me suspicious of a malignant growth. It seemed very probable that a growth might have existed for some time, subcortically to the orolingual area, in an ignorant laboring man, without having attracted special attention, and that sudden closing of one of the branches of the left middle cerebral artery might account for the sudden appearance of the paralysis and the disturbance in speech. After carefully studying the case for a number of weeks, I was unable to come to any positive conclusion in regard to the nature of the lesion. The man's condition was becoming worse and his headache was very troublesome, so that surgical aid seemed to offer the only hope of relief. I explained to the patient that he might not gain much from an operation beyond relief from pain, and that his paralysis and speech-defect might still persist. He left the matter entirely with me. I asked Dr. Rogers, the surgeon on duty at the hospital at the time, to see the case with me. We decided that an operation could do no harm, as all other means had failed to relieve the symptoms, especially the pain. January 17th was set for the operation. He was

reëxamined on the 16th. Dyn.: R., 52; L., 94. All other conditions were about the same as on the 2d inst., except that the patient was weaker than on that day.

OPERATION AND SURGICAL ASPECT OF THE CASE.

By Dr. Rogers.

January 17th, 12.30 P.M.: On removing a three-quarter inch button of bone from over the lower ends of the central convolutions, and enlarging the trephine opening to about one and a half inches in diameter, the dura seemed lax, and did not bulge. No pulsation of the brain was felt or seen. Dr. Eskridge applied the Keen double electrode, attached to a large Flemming faradic battery, to the lower portion of the exposed surface of the dura, but elicited no response from any muscles. On his carrying the electrodes a little higher, the thumb and fingers of the right hand flexed. After holding the electrodes in the same position a few seconds, the muscles of the right side of the neck contracted, the head turned to the right, and a slight convulsive movement occurred on the entire right side of the body, except in the muscles of the leg. On incising the dura over the supposed face center, the latter, over an area about three-fourths of an inch in diameter, seemed soft and degenerated. The broken-down area of the cortex, which looked cystic, was excised, without apparently cutting into the white substance of the brain, below. The brain was seen to pulsate as soon as the dura was incised. Gold foil, the size of the opening in the skull, was placed between the scalp and the dura and the wound completely closed. He made a rapid and uneventful recovery from the surgical operation.

MICROSCOPICAL EXAMINATION OF THE EXCISED PORTION OF THE CORTEX.

By Dr. Axtell.

The brain-cells are apparently lessened in number. They seem to be smaller than normal and to present open spaces about them, which are filled with fluid and granular material. The blood-vessels show slight thickening of intima and adventitia. The neuroglia is somewhat increased in amount, and shows an increase in its cellular elements. The pathologic diagnosis is local cerebritis.

CONTINUATION OF THE RECORD, WITH REMARKS

By Dr. Eskridge.

The degenerated portion of the cortex was circumscribed, about half an inch in diameter, and apparently limited to the left face area. The affected portion was much softer than the surrounding cortex, and, on cutting into it, it had a cystic appearance and contained a few drops of straw-colored watery fluid. The pia was firmly adherent to the cortex over the degenerated area. No muscular contraction occurred when the electrodes were applied to the dura over the affected portion of the cortex, nor when the electrodes were brought into direct contact with this portion of the brain after the dura had been incised, but that the face area was involved by the lesion seemed to be proved by the thumb and fingers of the right hand contracting on the electrodes being carried just above the area invaded by the pathologic process.

After the operation the lower right side of the face was almost completely paralyzed, but the tongue did not deviate much to the right on protrusion. The right hand was almost completely paralyzed for a few days. His power of speech-utterance was worse than before the operation, so that scarcely a word that he attempted to speak could be understood. Deglutition did not seem to be much affected. Tactile and localization sensations were lessened on the skin covering the affected muscles, but pain and temperature sensations remained nearly normal. He experienced no difficulty in understanding or thinking in speech. The clinical record after the operation shows nothing of any special importance. The temperature remained about the same in each axilla, and was practically normal after the first few days.

January 20th, the following notes were made: "Dyn.: R., 32; L. 86. Lower right side of the face, including nose, is completely paralyzed. The right eye can be opened and shut with the left, but the upper lid of this eye cannot be moved without moving the corresponding lid of the left eye. The tongue is protruded nearly in the median line. Pronunciation worse than before the operation. Localization is perverted in right hand, but normal over the face, except on right side of upper and lower lips. Temperature and pain sensations apparently normal everywhere. Tactile sensation seems very good, except in right hand and over right side of lips, where it is slightly lessened in acuteness." It will be observed that the right hand, three days after the operation, was about two-thirds as strong as it was immediately before, thus showing the hand-center had not been excised. From the 20th of January until about the 1st of March he scarcely showed any improvement. He did not seem to suffer much from the immediate effects of the operation, but he was so anemic and weak that he did not rally, gain strength, or put on flesh. He suffered a great deal from headache, was despondent and nervous, ate but little, had great difficulty in digesting his food. He continued weak and anemic for five or six weeks after the operation.

Early in March improvement became manifest. He began to utter his words more distinctly, his headache lessened and finally disappeared, he put on flesh, and soon looked much better in every way. He was now required to write a letter daily and to read aloud for an hour or so each day. He has made slight improvement in writing, but it is yet almost impossible to read what he has written. He, himself, has great difficulty in reading his own writing, except immediately after he has written. As he began to form many letters so that they could be made out, it was found that he misspelled and occasionally transposed phrases. It must be remembered, however, that he never learned to write well, and probably always spelled poorly.

Examination, May 15, 1896: The patient looks the picture of health, and seems bright and cheerful. His gait is good and he can walk briskly without scarcely showing any limp in the right leg. With eyes closed he walks backward and uses the right leg as well as the left. There is no ataxia, except in the right arm and hand. He uses the right hand and arm slowly and awkwardly. All the leg muscles are strong. Dyn.: R., 100; L., 115.

Knee-jerks both increased, right a little more than the left; ankle clonus and plantar reflexes absent; tendo-Achillis and cremaster reflexes present; abdominal reflexes absent; all the reflexes of the arms increased, the right more than the left; masseters absent; all general sensory phenomena normal. Hearing, taste, and smell present no points of especial interest.

Eyes: R. vision, $\frac{4}{6}$; L., $\frac{4}{6}$. Fields are normal. The pupils are normal, equal in size, and react readily to light and accommodation. All the external ocular muscles act normally. The fundi and disks present no pathologic changes, except that the disks look a little pale.

The right lower side of the face is wasted in comparison with the left. He says that his face was symmetrical before the beginning of his present trouble. The parts around the mouth, on casual inspection, seem drawn to the right, but this appearance is due to the wasting, as the center of the lips still remains in the median line. He is able to move the right corner of the mouth much more freely than he could before the operation. Both eyes close well at the same time, but he cannot close the right eye without closing the left. The tongue deviates slightly to the right in extreme protrusion. He is unable to whistle; formerly he could whistle quite well.

Speech: The speech-defect is of the same character in every particular as was noted at the former examination, but he articulates much better. With a decided effort he can slowly and deliberately pronounce most words. Sometimes it requires two or three attempts to pronounce a long word, but in the end he usually succeeds. The lips and tongue are not paralyzed, but ataxic. They present very much the same condition that is found in the muscles of the right hand and arm. He has no difficulty in thinking in speech. He still writes much worse than he did before the paralysis of the right hand occurred. The writing with the left hand is fairly good for one who never wrote even an ordinary hand. He does not transpose any letters. Simple words he spells and writes correctly. If a word is spelled for him, he does not write it any more rapidly or correctly than when he is allowed to spell it himself. The defect in writing seems almost entirely due to the ataxic condition of the muscles of the right hand and arm. His headache has entirely disappeared, and his mind is clearer, although specific medication was never resumed after the operation.

The results of the operation in this case fully justify its repetition in similar cases. There is no doubt that localized cerebritis acts as an irritant, giving rise to headache and interfering with cerebral function. Kussmaul and others give muscular wasting of the face, in connection with defect in speech, as one of the diagnostic symptoms of bulbar lesion, in contradistinction to one occurring above the nuclei of origin of the cranial nerves concerned in articulation and phonation. But few writers, so far, have laid much stress upon the fact that an irritative cortical lesion may cause rapid and pronounced wasting in the group of muscles involved. The second case reported in this series is a striking example of this. One of the chief symptoms between atrophy of the muscles from a nuclear lesion and from one in the cortex is that in the latter the affected muscles respond normally to electricity, while in the former they do not. The wasting from irritative cortical lesions is probably due to an inhibitory influence on the trophic centers, while that which occurs from a nuclear lesion is due to the direct effect on the trophic centers of the muscles themselves.

The defect of speech from orolingual paralysis will be considered more fully in a paper devoted to aphasia.

July 3, 1896, William E. was so well that he decided to leave the hospital and earn his own living. At this time, he talked so as to be readily understood, could communicate his thoughts in writing, walked with only a slight limp in the right leg, and used his right hand fairly well.

Nothing further was heard of him until the morning of July 8th, when he was found in his room in an unconscious condition and was supposed to be suffering from a poisonous dose of morphin, as his pupils were pinhole in size and the respiration was slow and irregular.

He was immediately taken to the county hospital, and I saw him shortly after his admission; 11.30 A.M., he was completely comatose; the pupils very small, equal in size, and did not respond to a strong light; the left eye diverged and turned slightly upward. Corneal reflex; R., absent; L., present. Knee-jerks, both enormously increased and attended with slight clonus. Ankle-clonus present, but slight, and a little more pronounced on the left side than on the right. The resident physician stated that when the patient was first brought into the hospital, the ankle clonus and the other deep reflexes were more marked than when I examined him. Plantar reflexes absent. Tendo-Achilles: R., slightly increased; L., decided and attended by slight clonus; cremaster and abdominal reflexes absent. All the deep reflexes of the arms, including the deltoid and pectoralis major, were greatly exaggerated, but more marked on the left than on the right side. The masseter reflexes were not tested. Pulse was 108, small and very compressible; respiration 14 per minute, intermittent, short, and spasmodic, or jerky, in character. One hour and a half before I saw him, his axillary temperature had been: R., 100.8°; L., 99.8°. At the time of my first visit, it was R., 102.2°; L., 102.2°. Unconsciousness was so profound as to make it impossible to test any form of sensation. The bladder was emptied by means of the catheter, and the urine found to be free from albumin or sugar. The lungs and heart presented no evidence of disease.

From the loss of the right corneal reflex, on account of the enormous increase of the deep reflexes, greater on one side (the left), the jerky character of the respiration, and the elevated temperature, without any renal or intrathoracic complications to account for it, especially as the temperature had increased about two degrees in 90 minutes, opium poisoning was excluded. Instead, a diagnosis of thrombotic occlusion of a vessel affecting the arterial blood supply to the right side of the pons was made.

At 6 P.M. the axillary temperature was: R., 104.2°; L., 104.2°. He gradually sank and died the next day about noon. The temperature did not go above 104.2°. It fell one degree in each axilla from 6 P.M. of the 8th to 6 A.M.

of the 9th, but rose to 104.2° just before his death, a few hours later.

Autopsy four hours after death.

On reflecting the scalp, the gold foil was found *in situ*, but it was perforated in several places, and adhesions between the dura and scalp had formed through the openings in the gold foil. There were no abnormal adhesions found between the dura and bone. At the seat of the operation, the membranes were found firmly adherent to each other and to the brain substance. No other adhesions, except the one just noted, were found between the dura and soft membranes. In the left middle cerebral artery, just peripheral to the point at which the anterior cerebral is given off, there was a patch of arteritis on its under and posterior surface about one-quarter of an inch in length and extending about half-way around the vessel. The coats of the vessel were thickened and roughened, but the lumen of the artery was not occluded. The anterior cerebral and right middle cerebral arteries appeared normal. The right posterior cerebral artery presented several patches of arteritis that completely encircled it. The right posterior choroid artery, which is a branch from the posterior cerebral, was completely occluded. The left posterior cerebral, the basilar, and vertebral arteries, presented no further evidence of disease beyond little whitish spots that were evidently the seat of beginning arteritis. The pia was readily stripped from the brain, except at the point of the operation, where it could not be detached without taking a portion of the cortex with it.

It was found that the dura had been incised, and the cortex scraped at a point situated at the lower end of the fissure of Roland, and that the adjacent portions of the cortex of the ascending frontal and ascending parietal convolutions had been invaded by the surgeon's spoon. The cortical substance immediately around the site of the operation of the convolutions was slightly softened and a little yellowish in appearance. On the under surface of the posterior portion of the operculum there was an area of yellowish softening about one-quarter of an inch in diameter and not more than one line in depth. The insula and the third frontal convolution were normal in appearance. In the left lenticular nucleus, at a point corresponding to the angle of the internal capsule, there was found an old cyst about one-quarter of an inch in diameter, and just behind this, with an intervening bridge of white, fibrous-looking tissue, another cyst of about the same size was discovered. The cysts contained a yellowish, flocculent, watery liquid, evidently the result of softening from arterial occlusion. The remainder of the left side of the cerebrum, the entire right cerebrum, and the whole of the cerebellum, presented no abnormal appearance. The crura seemed normal. On sectioning the pons and medulla, the entire right side of the pons and the upper portion of the medulla of the same side, showed evidence of marked vascular change. The tissue was less firm than on the opposite side, appeared edematous, with spots of hemorrhagic extravasation, which was in marked contrast to the corresponding structures on the left side.

MEDICAL PROGRESS.

The Effects of High Altitudes on the Blood.—SCHAUMAN and ROSENQUIST in the *Centralblatt f. Innere Medicin*, May 30, 1896, contribute a valuable paper to the better understanding of the effects of high altitudes on the human body. Up to the present time, most of the experimental work on this subject has been done by the French and Swiss, Viault, Regnard, Egger, Miescher, Mercier, and others. These investigators have definitely proved that by a relatively short residence in a high altitude, the number of red blood-cells per cubic millimeter is increased, the maximum being reached in from two to three weeks, and that a low region, this increase is soon lost.

Grawitz and Sahli have tried to explain this increase by saying that the blood in the dry high atmosphere became more concentrated through loss of some of its serum; but experiments with rabbits have failed to make good this claim, and Zuntz has pointed out that on account of the osmosis in the body, in order to increase the blood-cells 20 per cent., it would be necessary for a person to lose from twelve to fifteen pounds in weight, which does not take place. The explanation is, therefore, still to seek.

Schauman and Rosenquist experimented in the laboratory. A dog was enclosed in a glass chamber at a considerably diminished pressure of the atmosphere (450 to 480 mm. of mercury). The other characteristics of high altitudes were wanting, as the air in the chamber was moist and warm, and not very pure. Still in three weeks the blood count had increased from 5,000,000 to 7,200,000, and the hemoglobin from 68 to 80 per cent. Two months after the animal was again at liberty, these figures were still above normal; viz., 6,490,000 and 81 per cent.

The authors conclude that the effects of high altitude on the blood, is not due to dryness, but to rarefaction of the air; and that the increase in red blood-cells is an actual one, and not an increase relative to the serum. This is still further supported by the fact that the blood from the dog, after his removal from the rarefied chamber, and while the blood count was diminishing, often contained many "shadows" of blood-corpuscles—a condition which has been noticed after the injection of substances which disintegrate the blood.

An Extraordinary Retention in Utero of the Fetal Head.—In the *Centralblatt f. Gynäkologie*, 1896, No. 24, is mention of a case reported by TOTH of Budapest, in which the attending physician pulled so vigorously upon the breech of an eight month fetus that its neck parted, and the head remained in utero, despite all his exertions to remove it. The mother, a young III-para, recovered with some fever, and enjoyed good health for a year. During this time, irregular hemorrhages and foul-smelling discharge continued, followed by the occasional discharge of bones. At the end of sixteen months, the cervix was dilated, and the large bones of the skull, which remained, were removed. They were extensively adherent to the uterus, and the free hemorrhage which followed their removal was controlled by tamponade. The patient made a quick recovery. Such tolerance on the part of the uterus must be very unusual.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

SATURDAY, AUGUST 15, 1896.

THE CHARITIES COMMISSIONERS.

The recommendation which has been made by the framers of the Greater New York Constitution, that the most important Commissions be comprised in one individual, is to be heartily commended. The unity of the Charities Commissioners, instead of a trinity, as exists to-day, would, in all probability, have obviated the farce now being enacted in Bellevue Hospital under the present Board.

A single-headed commission would undoubtedly bring to the position an incumbent of sufficient intelligence to appreciate the fact that the duties of the office do not involve the exploiting of secret cures for drunkenness. Swelled though his head might be by the importance of his official functions, it would hardly reach such dimensions that he would deem it his province to investigate, for the medical profession, the efficacy of drugs and compounds for the purpose of adding a new remedy to our pharmaceutical list. Let us hope that he would have sufficient perspicacity to comprehend the fact that any conclusion that he, as a layman, might reach in such matters, even though he might previously have been a manufacturer of furniture, or even a harness-maker, would hardly possess sufficient scientific value to commend them to anyone, except, possibly, an interested stockholder or the poor, ignorant charity patient, whom it is his duty to protect from charlatanism and imposition.

But not only the illogical position in which the Commissioners have placed themselves, but also the great wrong they are doing, by lending the moral support of Bellevue Hospital to a secret, capitalized nostrum, has already been made clear to them in the columns of the News. The error of their way has been pointed out, and a method of retreat consistent with dignity and self-respect has been within their grasp. But each day of persistence in their present course is burning their bridges behind them; and the time is fast approaching when the profession and the community will rise in their indignation and insist that the present Board shall be wiped out. They are failing of their duty in one direction, while they overstep their prerogatives in another. As our esteemed contemporary, the *Medico-Surgical Bulletin*, says:

"We are determined that no injustice shall be inflicted on the pauper; that he shall not be experimented with in any way, but that, on the contrary, he shall receive the treatment which is his due, all the more so because he is defenseless. Stop this nostrum business at once, therefore, Mr. Commissioners, or you will find your heads in a worse hornet's nest than you ever came in contact with in your younger days."

THE FALSE AND THE TRUE IN PHYSICAL BEAUTY.

We sometimes imagine that the tedious "setting-up drill" of all systems of military training is mainly for the purpose of giving the lines of the regiment a uniformly erect appearance upon parade, chiefly a matter of display, but this is far from the truth. On the contrary, it is insisted upon so invariable because the experience of countless generations has shown that the elements which make up an erect, "soldierly" bearing are the very ones which indicate the development of the highest possible degree of vigor, of speed, and of endurance.

The same will be found true of the various regions and parts of the body. We will begin with a region where the standards are supposed to be entirely at variance, the waist line, whose flowing curves from armpit to hip are rightly regarded as forming the chief beauty of the trunk outline. Fashion and popular taste demand simply a rapid inward slope to as small a waist as possible, regardless of all other elements of the curve; physiology and hygiene denounce this as unhealthy and crippling. Beauty and health appear to be at loggerheads here. But it is only with a false ideal of beauty that there is any conflict; call in the artist, the anatomist, to settle the dispute, and he will instantly decide with the physiologist. The ideas of "beauty" of the fashion-plate, the modiste, and Mrs. Grundy, are often widely different from those of the artist, the architect, and the naturalist; and it is with the latter only, that we are concerned. We may well paraphrase Madame Roland and exclaim: "Oh Beauty, what crimes are committed in thy name!" In the vast majority of these conflicts between beauty and common sense, the fault lies in a false ideal of beauty. The ideal waist of the artist is that of the Venus de Milo, and every line of it fulfils to perfection the demands of the hygienist for the highest lung power, combined with ease and vigor of movement.

Another similar instance of conflict between grace and efficiency, is that between the popular and hygienic ideals of a beautiful foot. These differ widely indeed. The popular demand in a feminine foot is that it shall be a narrow, pointed elongated body curved, or more accurately humped, into a nearly horse-shoe shaped arch, the pillars of which are within a few inches of each other, and consist of the compressed tips of the toes, and a high narrow heel brought forward almost directly under the center of gravity. Its functions as an organ of support and locomotion are ruthlessly disregarded, and instead of a series long, low, graceful arches, it is distorted into the resemblance of a link of sausage pointed at one end, or a banana in opisthotonos.

The physician, the skilled pedestrian, denounce it as deformed, useless, painful, and almost disabled; and again, the artist cordially unites in their attack, and demands the very same outlines that they do.

The plan of the healthy, natural foot is an exquisite combination of arches—one long and low from the heel to the balls of the toes, the other short and high, crossing this at right angles a little in front of the ankle-joint. These are composed mainly of a number of wedge-shaped bones, but there is little that is "bony" or rigid about them, as their form is mainly preserved by the tension of three muscles of the leg, whose tendons attach themselves to both the upper and lower surface of their keystones in a most ingenious manner, if we may use such a term with becoming reverence. Thus the weight of the body is naturally supported upon the intersection of two graceful, yielding, living arches, which, by their expansion and contraction, give a beautiful, springy elasticity to the gait. But in order to do this, they must, like all other springs, expand so that the foot ought to become markedly both longer and wider when weight is placed upon it. For this change in form, the modern "pretty" shoe makes absolutely no adequate provision, and not only this, but by throwing a ridiculous peg-shaped heel far forward to give an appearance of shortness to the foot, the longitudional arch is completely broken, the weight thrown directly upon the sensitive instep, the center of gravity of the whole body disturbed, and the elasticity of the gait destroyed.

Mechanically, the human foot is one of the most exquisitely adjusted, effective, and most enduring instruments in the world—it will run down and outlive any hoof, pad, or paw that moves. Artistically, for beauty of outline, harmony of curves and dimples, and grace of movement, it is equally unsurpassed. Here again, beauty goes hand in hand with strength, and fashionable deformity with feebleness.

The beauty of finely molded shoulders and rounded arms, and tapering wrists, is dependent not upon the form of the bones, nor even upon the amount of adipose or fatty tissue—mere plumpness is not beauty—but upon the live contour and rippling grace of muscle.

As for beauty of complexion, although universally decried as only "skin deep," in its natural

and only truly attractive form, it affords one of the best and most reliable indices of health and vigor. It may be imitated, but no paints, cosmetics, or "local treatments" of any sort can begin to reproduce the rich, warm, living depth of coloring, the translucent creamy whiteness, and the velvety gloss of surface which is as absolutely dependent upon pure blood and springy muscle, as a red June rose is upon its vigorous stem and roots in a fertile soil. A fine complexion instead of a mere surface finish, is the exquisite blossom of health and purity throughout the entire body, and literally "goes to the bone" as its counterpart "ugliness" is proverbially declared to do. An artificial complexion usually deceives nobody but its wearer.

In that important realm of decorative art, dress, the coincidence between beauty and healthfulness is no less striking. From the Greek chiton and the Spanish mantilla to the graceful Persian divided skirt and mantle, which the celebrated Worth kept hanging upon the walls of his studio as his ideal of the beautiful in the feminine costume, the lines of artistic beauty and of hygienic utility coincide almost absolutely. The corset, the bell-skirt, with its "street-cleaning" attachment, the crippling multiplicity of petticoats, and the ridiculous bustle, are offenses alike against the canons of art and the rules of health.

LATEST DEVELOPMENTS OF THE ROENTGEN X-RAYS.

Improvements of great importance have been effected by the General Electrical Company of Berlin in the Röntgen apparatus, by the employment of the new vacuum tube devised by Dr. Max Levy, the engineer of the Company. It is now possible to inspect the interior of Highmore's antrum, the frontal sinuses, the throat, the heart, and the lungs, through the use of this tube and the fluorescent screen. Levy's vacuum tube contains two concave electrodes, with a disk of platinum midway between them tilted at an angle of forty-five degrees. The disk is coupled to one of the electrodes, and the wires of the induction coil are attached so that the anode is duplicated. The fluorescent screen used is about ten by eighteen inches in measurement. Its surface is covered by small crystals of platinocyanid of barium dusted on after covering it with some adhesive material. It has been found by several experimenters that impregnation of a cardboard surface with this or similar material does not furnish a screen that will be fluorescent. It is necessary that the crystalline form of the substance used should be retained, in order that the picture may be seen on the screen.

In the past, the utility of the skiagraphic process has been limited by the fact that it has been impossible to focus the rays with certainty to any required depth in the opaque subject. The result was experimental in every case, and not until the skiagraphic negative had been developed, after a tentative exposure to the invisible rays, could the operator know what he had obtained. By means of the screen, however, a definite view can be obtained at once, and a skiagraph need not be made at all. Immediate inspection is possible with Levy's tube and the screen. In a test made in the offices of the London *Lancet*, pictures of the contents of the thorax, of the neck, and of the stomach were shown, one after the other.

The practical utility of the apparatus is seen in certain cases of disease in which valuable knowledge was obtained by inspection of the screen. In a case of arteriosclerosis, in a man aged fifty-six years, the thickened condition of the radial and ulnar arteries was seen, as well as the doubly increased size of the aorta, and the fact of the descent of the diaphragm with each inspiration to a distance of only three-quarters of an inch was accurately observed. In another case, that of a young man aged twenty-six, who had suffered from a pulmonary hemorrhage a year and a half previously, shadows due to the calcification resulting from the old disease were seen in the right lung, while the other appeared normal. These results could not be reached by other methods of examination. The diagnosis of enlargement of the heart was confirmed in two cases of mitral disease by the enlarged shadows on the screen. One of these cases showed also great hypertrophy of the left ventricle. Calcification of the aorta was revealed in one case. The improved Röntgen apparatus has thus become valuable, in confirmation of diagnosis

not only, but also in deciding with precision concerning existing conditions, which otherwise would be obscure and puzzling.

ECHOES AND NEWS.

Meeting of the British Medical Association for 1897.—The British Medical Association at its recent meeting in Carlisle accepted unanimously the invitation of the Montreal branch to meet in Montreal in 1897. The date of the meeting has not yet been positively decided upon, but will probably be the latter part of August.

Prince Bismarck an M.D.—On the occasion of the twentieth anniversary, on July 16th, of the opening of the Imperial Office of Health in the city of Jena, the faculty of the university conferred upon Prince Bismarck the honorary degree of M.D. Prince Bismarck is now possessed of all the doctor's degrees in the gift of the German universities.

Poisoned by a Woman's Decayed Tooth.—Dr. D. C. Sutherland, a dentist of Baltimore, is suffering from blood-poisoning, which he contracted while extracting a much-decayed tooth, a piece of which broke off and flew into Dr. Sutherland's left eye. Symptoms of blood-poisoning appeared, and it is feared that the eye may have to be removed.

Dr. Love and the Marion-Sims College.—Dr. I. N. Love has found it incumbent on him to sever his connection with the Marion-Sims College of Medicine of St. Louis. The members of the Faculty of that institution embrace the occasion to express their appreciation of his past services and to extend to him their hope that in all his future connections he will find both pleasure and profit.

Formalin in Ophthalmic Practice.—Dr. Dahrenstaedt, an eye specialist, has employed formalin with extraordinary success in two cases of ulcus serpens corneæ with hypopyon. Both of the patients came under treatment on the same day. Instillations of formalin, one part in two thousand, were made every hour from six in the morning until eleven in the evening, occasionally a drop of atropin solution being also injected. In five or six days both eyes were quite out of danger, and after a fortnight the healing process is still going on favorably and without irritation.

Veratrum Viride in Eclampsia.—Dr. Charles Jewett of Brooklyn, N. Y., is engaged in collecting statistics with reference to the value of veratrum viride in the treatment of puerperal convulsions. He will be glad to receive brief reports of cases from physicians who have had experience with the drug. What is especially desired is a statement of the number of convulsions in each case before the veratrum was administered, the quantity of the drug used, the mode of administration, and the results obtained. Due credit will be given.—*Brooklyn Medical Journal.*

The Difference Between the Highwayman and the Quack.—The ancient highwayman was a considerate person. His demands might sometimes seem urgent, but they kept within certain bounds. He gave you a choice of evils. If you would surrender your money, you might keep your life; and doubtless he frequently praised himself for easing you of that which is often a snare. He merely demanded your money or your life. The modern quack doctor is a much more bloodthirsty character. He has no such scruples as the highwayman, and no such moderation in his demands. With him there is no alternative. He makes his victim pay him for robbing him of his health. He wants both money and life.

The Lowest Possible Death-Rate.—The *American Practitioner* asks the question, What is now regarded as the minimum death-rate for an urban population? The late Dr. Parkes fixed 17 per 1000 as the "mortality incident to human nature," and in his time—the infancy of hygiene and sanitation—even that figure seemed Utopian. But what shall it be now fixed at in view of the reduced rate in Greater London? In 1894 the death-rate had fallen from 20.5 for the decennium, 1881–90, to 17.7 per 1000; and last year, 1895, when the mean was 19.7, there were sanitary areas in the great metropolis with the following figures: Wandsworth, 14.8; Lee, 14.5; Lewisham, 14.4; Stoke Newington, 13.4; and Hampstead, 12.

Intrinsic Value of Public Parks.—That public parks in cities are good investments from a sanitary standpoint goes without saying. That they are also profitable as a pecuniary investment is shown in a recent report by J. Clyde Power, landscape engineer, recommending extensions of the park system in Indianapolis. He cites New York as a notable instance of the great increase of value accruing to land in the vicinity of parks. In 1856 the assessed valuation of the three wards adjoining Central Park was $20,429,565; in 1873 it was $236,081,515—a gain in seventeen years of $215,651,950. The natural average increase of three other wards in the city, taken from the total excepting those adjoining the park, showed only $53,000,000, thus proving the earning capacity of the park to be $183,081,515. In Brooklyn, in 1864, Prospect Park containing 515 acres, was acquired, and the increase in the valuation of surrounding property in three years was thirty-eight per cent.

Medical Progress in Japan.—Competent European critics announce that the medical service of the Japanese army in the late war between Japan and China was conducted with a thoroughness and efficiency that give it a first rank even among the western nations. This is another evidence of the rapid strides that Japan is making in her modern civilization. It is hardly forty years since medicine in Japan was represented by superstition and charlatanism that surpassed even the crude appliances of the Middle Ages. Now the medical faculty of Tokyo University is said to be as perfectly organized and administered as that of Berlin University. The medical classes in the University and schools are crowded with students who zealously covet the diploma of Scholar in Medical Science, which is the equivalent for the American M.D. Hospitals for all classes of diseases have been instituted in Tokyo,

and the chemical and bacteriological laboratories are abreast in their work with Germany and France.

Doctors and Lawyers.—In the speech of Mr. Justice Vaughan Williams, at the annual presentation of prizes to the students of the Charing Cross Hospital Medical School, he declared that there was a considerable affinity between the professions of law and medicine. Both required the same qualities, both were the recipients of confidences from their clients, and he would add that the clients rarely found their confidences misplaced. He, as a lawyer, often came into contact with doctors in the law courts, where the most important issues were often determined solely on the evidence of medical experts, who were, for the most part, safe guides in the administration of justice. One point, however, in which the professions differed, was that the medical profession was essentially progressive, while the legal profession was in a sense stationary. If the doctors of the last century came to life again, they would know comparatively nothing of contemporary medical science, but if the judges of former times were installed in the law courts to-morrow, they would try the cases quite as well, if not better, than the judges of to-day.—*British Medical Journal.*

Baths in the Public Schools.—While this subject is being agitated in Boston and some other parts of this country, the city of Milan has brought it to a practical trial. The experiment was recently made in that city at one of the communal schools, in the presence of civic representatives, of the municipal medical adviser, Dr. Uffreduzzi, and of Dr. Sacchi, of the clinical staff of the Ospedale Maggiore. Forty boys, accommodated in a disrobing-room fitted with benches, were made to strip, and covered only by their large drying towels, were led in relays of five to a contiguous hall, where they were all made to take the douche. Thereafter, provided with soap, they cleansed themselves from head to foot with fresh water and returned to the disrobing-room to dry and dress themselves. The mechanism of the douche is simple. Five small reservoirs are suspended in a row at a height of two and a half yards from the floor and furnished, laterally, with two chains. Pulling that on the right the boy is douched *a colonna* (in a volume of water), or pulling that on the left he is douched *a pioggia* (in a shower). The locale has been modeled on the lines of similar locales in barracks, and may be heated in winter.

Ten Hygienic Aphorisms.—The late Dr. Frank H. Hamilton, of Bellevue Hospital, is said to have framed the following decalogue of health precepts: (1) "The best thing for the insides of a man is the outside of a horse. (2) Blessed is he who invented sleep—but thrice blessed the man who will invent a cure for thinking. (3) Light gives a bronzed or tan color to the skin; but where it uproots the lily it plants the rose. (4) The lives of most men are in their own hands, and, as a rule, the just verdict after death would be—felo de se. (5) Health must be earned—it can seldom be bought. (6) A change of air is less valuable than a change of scene. The air is changed every time the wind is changed. (7) Mold and decaying vegetables in a cellar weave shrouds for the upper chambers. (8) Dirt, debauchery, disease, and death, are successive links in the same chain. (9) Calisthenics may be very genteel, and romping very ungenteel, but one is the shadow, the other the substance, of healthful exercise. (10) Girls need health as much—nay, more than boys. They can only obtain it as boys do, by running, tumbling—by all sorts of innocent vagrancy, At least once a day girls should have their halters taken off, the bars let down, and be turned loose like young colts."

The Anti-Science Crusade.—Under the specious plea of preventing cruelty to animals, a crusade is constantly being waged against science and common sense. The crusade against physiological inquiry is really one against the acquisition of knowledge by which life can be saved, and recent antiscientific agitators go so far as to urge that patients in hospitals should be "protected" against treatment by which their diseases can be cured. "Knowledge" is often said to be "power;" and the particular form of knowledge against the attaining of which these onslaughts continue to be made has indeed shown itself to be a power in the saving of life. When one serious disease comes on the top of another, then it is apt to go hard with the patient, and for years back it has been found that of all the complications of convalescence from scarlet fever, the occurrence of diphtheria has been the most terrible. Far more than half of the patients so attacked died until the introduction of antitoxin. Then the whole aspect of affairs was changed, for the death-rate fell, so soon as antitoxin was used in treating the disease, from an average of 63.0 per cent. during the preceding three years, to one which at the outside, even after deducting the mild cases, was not more than 7.5 per cent. This is sufficiently striking, but since the publication of the official report even better results have been obtained, long series of cases having occurred without any death at all. Now at what expense of cruelty have these results been obtained? A few healthy old horses which, if not used for this purpose, would either have already gone to the knackers' yard, or would still be enduring the hard fate which old horses must suffer when they have to earn their living by labor in the streets, are now well housed, well fed, and well groomed, on the one condition that they now and again put up with such a bleeding as, not so long ago, was voluntarily undergone by healthy men as part of the routine of spring and autumn. Yet because this thing goes by the name of vivisection, these writers howl, and would leave the ignorant to demand that these horses should be restored to the miseries of the streets, and that these children should again be handed over to the most cruel of all deaths.—*British Medical Journal.*

CIRCULAR LETTER.

THE DEATH OF GENERAL FESSENDEN.

To the Medical Officers of the U. S. Marine Hospital Service:

IT is with regret that I have to announce to the medical officers of the service, the death, on the 23d inst., from a complication of heart and kidney affections, of Surgeon

Charles Stewart Davies Fessenden. Surgeon Fessenden was the senior surgeon of the corps, having served since April 4, 1861—a period of more than thirty-five years. He was born in Portland, Me., February 23, 1828, and was of a family noted in the annals of his native State and the nation. His father, General Samuel Fessenden, was for many years a leader at the bar of Maine, and his eldest brother, William Pitt Fessenden, was the distinguished senator of that State, and during the administration of President Lincoln became Secretary of the Treasury. Two nephews of Surgeon Fessenden rose to the rank of brigadier-general during the Civil War, and others have been prominent in private life, two of them in the profession of medicine.

Surgeon Fessenden was fitted for college at the Portland Academy, and in 1844 entered Harvard University, where he pursued his studies for one year. Leaving Harvard, he became a student at Bowdoin College, from whence he was graduated in 1848.

He studied medicine under Charles W. Thomas, M.D., of Portland, Maine, and attending medical lectures at the Medical School of Maine, and also in New York, was graduated in 1851 from the Medical School of Maine. From 1853 to 1856 he was physician in charge of the Portland City Hospital, after which date he became a private practitioner until his appointment as surgeon in the Marine Hospital Service, in 1861.

During the period of his membership in the corps, he served as commanding officer at the ports of Portland, Me.; New York, N. Y., St. Louis, Mo.; Norfolk, Va.; Louisville, Ky., and Mobile, Ala. During this period he was also a member of three boards of medical officers convened for the examination of applicants for the Service, and of eight boards convened for the physical examination of candidates for admission to the Revenue Cutter Service, besides serving on various special details as inspector.

On account of the failure of his health in the fall of 1895, he was ordered to appear before a board of medical officers for physical examination, and, in accordance with the report of the board, was placed on waiting orders November 22, 1895.

During the few months which intervened between this date and his demise, Surgeon Fessenden resided at Salem, Mass., at which place his death occurred.

Respectfully yours,

WALTER WYMAN,

Supervising Surgeon-General M. H. S.

SPECIAL ARTICLE.

POINTS OF INTEREST TO MEDICAL MEN VISITING PARIS.

BY F. O. CHAMBERLAIN, M.D.,
OF PARIS.

ALTHOUGH there are among the traveling public annually visiting Paris a large number of American practitioners and students of medicine, very few see anything of medical work and progress in this great center. Unfamiliarity with the language is one of the chief deterrents, and limited time another; yet, in spite of these, the visitor could still derive much pleasure and considerable profit from an inspection of the clinical field, were he provided with the information requisite for his proper guidance. It is with the view of supplying, in some degree, this information that the writer, an American practitioner in Paris, takes pleasure in presenting, through the columns of the MEDICAL NEWS, certain points for the consideration of his colleagues coming abroad.

The twenty-five special and general municipal hospitals, which are open to the visitor, are divided about equally between the right and the left banks of the Seine, and are situated, with few exceptions, at a considerable distance from each other. For this reason, a central location, such as the vicinity of the Opéra, will be found to be most convenient for the visitor, unless he should wish to follow regularly the work of some special service. Should expense be a matter of consideration, accommodation may be found at a more moderate rate upon the left bank of the Seine. Upon that side of the river are situated the buildings of the Ecole de Médecine in the street of the same name. The faculty consists of thirty-four professors, with thirty-seven assistant professors, in active service. The students number nearly five thousand. There is no hospital connected immediately with the school, but the following permanent official clinics (Cliniques de la Faculté) are conducted by professors of the faculty:

With the exception of the obstetrical services (for which non-transferable cards are delivered gratuitously upon application at the office of the Secretary of the Faculty), the visiting medical man is admitted to all of the official clinics without formality of any kind, Much of the surgical work in the Paris hospital ampitheaters is performed under conditions similar to those obtaining elsewhere, but in the small rooms used for abdominal and most gynecological operations, the visitor is allowed the same freedom and facilities for viewing the work as those enjoyed by the house staff or the operators' assistants, a privilege less freely accorded the stranger in other countries.

For changes in the official program, the visitor should consult the posters (Tableaux des Cours et Cliniques de la Faculté) in the courtyard of the Ecole de Médecine. Copies may usually be obtained for a small gratuity, through the uniformed janitor in the hall (10 A.M. to 4 P.M.) leading to the Secretary's office, which, like that of the Dean, is in the school buildings. The Dean receives on Wednesday from 9 to 10.30 A.M., and the Secretary on Tuesday, Thursday, and Saturday, from 12 to 1 and from 2 to 3 P.M. The time at the disposal of these officers is so limited that the visitor desiring to apply for special information or favors had best do so by letter, or verbally through the First Assistant (Monsieur Lesieur) at the Secretary's office, window No. 1, Bureau de Reuseignements, 10 A.M. to 4 P.M.

During the School vacation, beginning in August and ending in October, the official clinics are discontinued. However, the visitor so inclined will find ample opportunity for observing work in the Paris hospitals at all seasons. Besides the Cliniques de la Faculté, there are

many services at which the visiting medical man is made welcome upon the presentation of his card. Of these services, the following are some of the most interesting, on account of the eminence of the men in charge, the organization of the work, or the novelty of the methods pursued:

Hôpital de la Salpêtrière.—Mental diseases, Dr. Déjerine, Thursday, 5 P.M.; Electrotherapy, Dr. Vigouroux, Tuesday, Thursday, Saturday, 12 to 3 P.M.

Hôpital Saint Antoine.—Nervous Diseases, Drs. Ballet and Brissaud; General Medicine, Dr. Hanot. An address upon the Medical Clinics of Paris will be delivered by Dr. Hanot, Tuesday, 5 P.M., in the amphitheatre of the hospital.

Hôpital Tenon.—Surgery, Dr. Tuffier, Tuesday, Thursday, Saturday, 10 A.M.

Hôpital Trousseau.—Diphtheria, Dr. Hutinel, Serumtherapy on an extensive scale.

Hôpital Necker.—Surgery, Dr. Le Dentu, Tuesday, Thursday, Saturday, 9 A.M.; Abdominal Operations, Dr. Le Dentu, Thursday, 9 A.M.; Genito-urinary, Dr. Guyon, Wednesday, Saturday, 9 A.M.

Hôpital des Enfants Malades.—Medical, Dr. Grancher, Tuesday, Saturday, 4 P.M.

Hôpital Laennec.—Therapeutical, Dr. Landouzy, Thursday, 10 A.M.

Hôtel Dieu.—Surgical, Dr. Duplay, Tuesday, Friday, 9.30 A.M.; Abdominal operations, Dr. Duplay, Thursday, 9.30 A.M.; Medical, Dr. Charrin, Monday, Friday, 10 A.M.; Ophthalmological, Dr. Panas, Monday, 9 A.M.; Ophthalmological Operations, Monday, 10 A.M.

Hôpital Saint Antoine.—Medical, Dr. Hayem, Tuesday, Saturday, 10 A.M.

Hôpital Sainte Anne.—Mental Diseases, Dr. Jaffroy, Wednesday, Saturday, 9.30 A.M.

Hôpital Saint Louis.—Cutaneous and Syphilitic Diseases, Drs. Besnier, Du Castel, and Hallopeau. The facilities at the St. Louis for the practical study of syphilis and diseases of the skin are unequaled. In addition to immense clinical material and a corps of specialists of international reputation, this hospital possesses a museum containing a remarkable and admirably arranged collection of wax casts, representing cutaneous lesions of great variety and in all stages. Surgery, Dr. Richelot; operations in the Pavillon d'Isolement several times weekly, in the morning chiefly gynecological, and illustrating certain points of technic original with the operator.

For full information respecting the above-mentioned services, the visitor should apply at the respective hospitals, ask the janitor to direct him to the service required, and there ascertain particulars from the interne on duty. Of the numerous private clinics, one of the most interesting is that of Dr. Apostoli, No. 19 Rue du Jour (Tuesday, Thursday, Saturday, 5 to 7 P.M.), where several thousand cases annually of uterine fibroids are treated by the Apostoli method of galvano-cauterization. Here also may be seen numerous patients under treatment by the new method of alternating currents of great intensity. At No. 3 Rue Christine may be seen (for hours of admission apply at clinic) Dr. Fort's so-called linear electrolytic method of dilating urethral strictures. The Institut Pasteur, No. 25 Rue Dutot, may be visited by permission of the Director on the premises. This institution is not connected with the medical school, and foreigners are admitted, under certain conditions, to work in its laboratories. Information concerning these conditions, however, would be of interest only to those desiring to pursue continuously special work, and would therefore be beyond the scope of the present description.

Hospital.	Clinic.	Days.	Hour.	Professor.
Charité. Rue Jacob.	Surgical. Medical.	Mon. Wed. Fri. Tues. Sat.	9.30 A. M. 10.00 "	Tillaux. Patain.

Saint Louis. Rue Bichat.	Cutaneous and Syphilitic. Diseases of Scalp. Dermatological Operations.	Wednesday. Thursday. Thursday.	11.00 A. M. 9.00 " 10.30 "	Fournier. " "
Salpêtrière. Boulevard de l'Hôpital.	Diseases of Nervous System.	Tues. Fri.	10.00 A. M.	Raymond.
Clinique d'Accouchements. Rue d'Assas.	Obstetrical visit.	Daily.	9.00 A. M.	Tarnier. (Bar, substitute).
Clinique Baudelocque. Boulevard de Port Royal.	Obstetrical visit.	Daily.	9.00 A. M.	Pinard.

mirable clinical course in nervous pathology is conducted at this hospital during the winter months by Dr. Ballet, Sunday, 10 A.M., Diseases of the Brain; and by Dr. Brissaud, Thursday, 10 A.M., Diseases of the Spinal Cord.

Hôpital des Enfants Malades.—Diphtheria, Dr. Sevestre, Serumtherapy on an extensive scale.

Hôpital Broca (Rue Broca).—Gynecology, Dr. Pozzi, operations in the morning, two or three times weekly.

Hôpital Beaujon (Rue du Faubourg St. Honore).—Surgery, Dr. Lucas-Championnière, Abdominal Operations in the morning, twice weekly.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.

Sixty-fourth Annual Meeting, held in Carlisle, England, July 28, 29, 30, 31, 1896.

FIRST DAY, JULY 28TH.

DR. HENRY BARNES delivered the President's address upon

THE MEDICAL HISTORY OF CARLISLE.

After referring to the power and influence of the British Medical Association, which he pronounced the largest and most powerful medical society which the world has ever known, he offered a hearty and cordial welcome to the

assembled members. The great purpose which had caused such a large body of men to come together under one name was to render our profession of the highest service, not only to the individual but the state, by taking our share and giving our advice in the framing of laws, in the regulation of charities, and by the elevation of all that constitute the education of a man of science, the physician, the surgeon, or the guardian of the public health. He then entertained his hearers with an elaborate account of the medical history of the City of Carlisle. It is one of the oldest cities in the British empire, and in referring to the early struggles of medicine within its limits, the author presented a bird's-eye view of the progress of medicine throughout the entire British islands. He dwelt at some length upon the value of the work of his predecessors, and of the debt that posterity owes to them. Carlisle had suffered from numerous visits of the plague, and had been sorely afflicted with epidemics of smallpox. The mortality from the latter disease at the end of the last century accounted for nearly one out of every seven deaths in Carlisle. Since that period it has been a well-vaccinated community, and now the disease is almost entirely unknown. The most distinguished physicians during the latter part of the last century were Dr. Wm. Brownrigg and Dr. Heysham. Dr. Heysham conceived the idea of collecting statistics of mortality, and by carefully recording the births, marriages, diseases, and deaths of the people, he accumulated the data upon which the "Carlisle Tables of Mortality" were based. The value of the Carlisle tables were speedily recognized, and one by one the leading life insurance companies, both in England and America, adopted them as the basis of their calculations.

Second Day, July 29th.

Sir Dyce Duckworth delivered the address in medicine, upon

the prognosis of disease.

In dwelling upon the importance of the subject of prognosis, he said that our minds have been probably too exclusively intent on acquiring knowledge of facts, and few among us have had time to apprehend the great general laws which underlie and govern them. The education of to-day is perhaps rather overladen with details, and somewhat barren of the inculcation of general principles. We must, if we are to be great in medicine, sometimes lift our eyes from the microscope and away from the engrossing researches of laboratories, and rising to a higher platform, survey the large fields which lie before and beyond us. We need both the talent of the ancient philosopher, who had an eye for general truth and the qualities of the modern observer, whose eyes are so intently set on particular facts. The problem now before the profession is to combine these in due harmony, and by the light of our most recent attainments, to cast our eyes forward and foresee the result of disease. No two cases being alike, we must have regard as to what disease means to the particular individual under consideration.

In cases of enteric fever, obese and elderly patients are bad subjects. The existence of chronic renal disease is incompatible with recovery from the continued fevers, and the presence of cardiac valvular disease adds greatly to the danger therefrom. Meteorism, delirium, and tremor are also of serious import, indicating failure of nervous power. Early hemorrhage is unimportant; late hemorrhage signifies exhaustion and deep ulceration of the bowel. Vomiting in the third week may be the precursor of peritonitis. Epistaxis is not serious unless profuse, when it may prove fatal. Abundant eruption of the papules does not denote any special gravity, and *per contra*, is no ground for belief that the case is a mild one. Excessive diarrhea is unfavorable. Perspirations, apart from other severe indications of weakness, are not important.

The malignant varieties of the exanthemata and of diphtheria admit only of the worst prognosis at any age and under all conditions. Prognosis is grave in the exanthemata, according to the early treatment, age of the patient, and the abundance of the eruption. High fever, delirium, hemorrhages, membranous angina, laryngitis, and parotid bubo are of evil augury in scarlatina, likewise suppression of urine from intense toxic glomerular nephritis. In the milder forms of scarlatino-polyarthritis, the prognosis is good. Purulent arthritis is almost uniformly fatal, unless confined ultimately to one joint. Capillary bronchitis and a collapse of large tracts of the lungs constitute the worst symptoms of measles in children. Recent experiences of influenza have taught us the special dangers of the peculiar pneumonia of that malady in the case of persons past middle life, and of the grave cardiac asthenia that may long persist.

Prognosis in diphtheria is certainly less serious now than was the case five and twenty years ago, and we note the exceptional danger to children under two years of age. Early tracheotomy, with aseptic treatment and intelligent nursing, has alone saved myriads of lives. Antitoxin treatment, in my experience, has proved of decided value in diminishing the death-rate. If a week elapse without laryngeal complications, we may fairly hope that the larynx may escape invasion by the membrane. After this, our anxiety relates to the welfare of the heart and of the nervous power of the patient. The spread of specific neuritis, with its varied symptoms, constitutes a danger sometimes little short of that induced by laryngitis. Nasal diphtheria should always excite concern. Delirium in diphtheria is also a bad sign. There is some risk of serious symptoms due to systematic intoxication in the adult, and more danger from laryngeal infection in the child.

According to Kanthack and Lloyd well-marked leucocytosis, gradually falling, together with decline of temperature indicates a good reaction and justifies a favorable prognosis. Low leucocytosis, or an absence of this, with fever, is a bad sign. High leucocytosis with subnormal temperature is always a bad augury. Other observers, however, are not in agreement on these points.

If variola attacks persons with Bright's Disease a fatal issue is certain. The eleventh or twelfth day is the most critical and laryngeal or pulmonary complications are the most fatal.

Erysipelas is likely to prove fatal if it starts in with severe constitutional disturbance and vomiting, especially

in the aged and in previously intemperate persons. In the newborn, if the naval is attacked, fatal issue is common.

In regard to tetanus, our experience of specific antitoxin treatment is as yet insufficient to enable us to form a decided opinion of its value, but it appears to be encouraging.

If organisms be present in the blood of a patient and capable of cultivation from it (pyemia and septicemia) the prognosis is bad.

Prognosis in relation to tuberculosis is a large question and the factors on which determination depends vary greatly with the individual and his environment. Undoubtedly, the prognosis of all disorders of a tuberculous nature admits of a more hopeful view at present than formerly. Rational treatment, followed upon exact pathology, explains why this is so. The tissue resistance of the individual counts for much. Hughes-Bennett taught, and I think correctly, that no disease was so often recovered from as tuberculosis. Peritoneal tuberculosis often ends favorably. Meningeal tuberculosis is the most deadly of all forms and is but rarely survived. The genito-urinary forms are all of grave import. General miliary tuberculosis is as fatal as any malignant disease of which we have knowledge. Without doubt a gouty habit of body tends to inhibit and retard tuberculous processes. Valvular heart disease with hypertrophy and cardiac dilatation induce pulmonary congestion and the power to be inhibitory. Pregnancy retards active invasion in the lungs, lactation aggravates it. Pulmonary emphysema, asthma and chronic bronchitis delay the course of tuberculosis.

In diabetes we have to deal with two main classes of patients, the lean and the fat. The former present the worst cases, the disorder being more or less acute. As is now well recognized, the younger the patient, the worse the prognosis. Every additional decade of years helps toward a less serious immediate outlook. Speaking, generally, after forty years of age the outlook becomes less serious. Chronic cases of diabetes in the elderely may get on fairly well in presence of fine constitutions for thirty years. I have never known recovery from coma in any instance.

In rheumatic fever, if the seventh or eighth day be passed and no cardiac complication has supervened, we may not expect any form of carditis or of pericarditis, but if a relapse occurs, we may meet with this as a manifestation of the fresh attack.

In typhlitis many cases recover under judicious medical treatment. Perityphlitic abscess, if opened carefully, about the ninth or tenth day, generally heals favorably. Earlier surgical interference is very apt to lead to a fatal issue by toxic peritonitis.

In few diseases is the question of prognosis so important as in lobar pneumonia. All practical physicians now agree that a sthenic single pneumonia in a previously healthy young man gets well. Single or double pneumonia in a drunkard is fatal. Herpes labialis is a sign of good augury in a great majority of patients, and mostly accompanies cases in which a sharp crisis occurs on the sixth day. Abundant rusty sputa, bright in color, in a lean, even if elderly, patient are a good sign. Sweating and moderate diarrhea at the time of crisis are also favorable indications. Modern research has shown that leucocytosis is commonly of favorable import in pneumonia, and both laboratory experiments and clinical inquiry attest the value of this indication. Absence of leucocytosis is commonly a bad sign in any case. In diseases of the heart, the outlook is generally better than it was half a century ago. Pericarditis of rheumatic nature is very rarely fatal *per se*. With the practice of aseptic surgery purulent carditis is no longer to be regarded as necessarily fatal. Tuberculous pericarditis may be rather protracted, but is beyond recovery. Pneumopericardium is commonly fatal within two days. The principles on which the prognosis is framed in valvular disease are now well understood. All depends on the constitution, powers, habits, and environment as regards the integrity and nutrition of the cardiac muscular fibers. Intelligent treatment, instigated by accurate physiological research, has much to do with securing long immunity from fatal issues in all the varied evolutions of this disease.

Pernicious anemia admits now of less grave prognosis than formerly, owing to treatment with arsenic and marrow. Relapses are common. Osler knows of no case in males that remained well for five years.

In chronic parenchymatous nephritis, I have long been convinced that there is great variation in the course and outcome; and while some patients rapidly pass into conditions beyond recovery, others hold on for months, so long as care is taken in all respects. We think less gravely of uremia than our preceptors were wont to do, and by modern treatment with drugs, and occasionally by the older treatment in venasection, we find this grave condition more amenable to treatment.

In neuritis, of the whole group of conditions—a somewhat large and varied one—our prognosis is guided by consideration of the etiology and personal factors of the case. Cases often last for months and years, but the results are often quite remarkable if treatment be persisted in. Endemic neuritis, or beriberi, if early treated, is not so serious a malady as is commonly supposed.

Dr. Dickinson says that "the tongue has a whole book of prognostics written upon its surface." Among the conditions of the tongue, which favor a satisfactory prognosis in any case of any disease, are to be noted recovery of moisture and a cleaning of fur from the tip and edges toward the dorsal.

The author closed with the words of Hippocrates: "It appears to me a most excellent thing for the physician to cultivate prognosis; and he will manage the case best who has foreseen what is to happen from the present state of matters."

Third Day, July 30th.

Roderick Maclaren, M.D., delivered the address in surgery. His subject was

PREVENTIVE SURGERY.

By preventive surgery must be understood operative work which is entered upon or undertaken for some risk or sequence which we expect to result from an existing

condition, and not what is actually present at the time. It was formerly alleged, by men of great capacity and intellect, that such operations were attended by a greater mortality than operations of necessity; nature was endowed by them with the power of accommodating itself to the inevitable but of resenting mere expediency. We should be able to say to a patient, If you allow what now exists to continue you will experience certain definite unfortunate consequences. Our technic ought to be perfect, for though mistakes and oversights may sometimes be excusable in operations of emergency, in preventive operations they should have no place.

A large amount of preventive surgery has a causal relation to the throat and naso-pharynx. Enlarged tonsils and adenoid growths check growth and nutrition. It is often very striking to see the growth and development which follow the removal of large tonsils or adenoids. Few operations give so good results with so little risk or trouble. It should be the rule to operate on every discharging ear that does not get well by treatment. The mastoid cavities should be laid open, all diseased bone removed, all unwholesome structures scraped away, and everything made suitable for speedy healing.

Herniæ offer a field for preventive surgery, but not every hernia should necessarily be subjected to operation. A properly adjusted truss will relieve all symptoms in the majority of cases and will cure many. But among the miseries which may make long life a burden to its possessor there are none greater than those resulting from an enlarged prostate. Supra-pubic cystotomy with removal of enlarged prostate is at present the operation to be first considered. The resulting mortality is small, not more than ten per cent., and it must be kept in mind that the condition is a very fatal one. The operation of removing the testicles for enlarged prostate is too new, and the cases too few, to allow of any decided opinion as to its merits.

An opinion strongly held, both here and in America, by men whose surgical work entitles their views to the highest possible respect, is that every appendix vermiformis which has given rise to morbid symptoms should be cut down upon and removed when in a quiescent state.

Another disease holds out the prospect of a wide field for the extension of the preventive principle, viz., carcinoma. In the future a preventive surgery founded on fuller knowledge will do for cancer what we are steadily doing for so many other diseases—compress it within narrowing limits.

Perhaps the besetting sin of surgery is that it has a narrowing tendency. In preventive surgery we have a tendency in an opposite direction. This tendency brings us into immediate contact with what the physician and general practitioner are doing, making our life and work a portion of the vast organization for the prolongation of existence, and still further associates us with the great mass of scientific and intellectual advancement which lies outside the limits of any profession, of any nation, and of any time.

(To be continued).

TENTH ANNUAL MEETING OF THE AMERICAN ORTHOPEDIC ASSOCIATION.

Held in Buffalo, May 19, 20, and 21, 1896.

ROYAL WHITMAN, M.D., of New York, President.

FIRST DAY, MAY 19TH.

L. A. WEIGEL, M.D., of Rochester, read a paper on

THE RATIONALE OF GYMNASTIC EXERCISE AND PRESSURE CORRECTION IN THE TREATMENT OF SCOLIOSIS.

He summarized his views as follows: (1) Gymnastic exercise as an exclusive method of treatment must be limited to the very early stages, and to deformities which are postural, pure and simple; (2) exercises of all kinds are insufficient, even in comparatively mild cases; (3) treatment by mobilizing the spine should precede any attempt to develop the muscles; (4) removal of the superincumbent weight is the important part of the treatment, and is of great value in sustaining the effects of exercise; (5) over-development is to be avoided; and (6) empiricism should have no part in the treatment of scoliosis.

JACOB TESCHNER, M.D., of New York, present by invitation, read a paper on

THE RAPID CURE OF ROTARY LATERAL CURVATURE OF THE SPINE, AND OTHER POSTURAL DEFORMITIES, BY MEANS OF THOROUGH DEVELOPMENT, AND CORRECTIVE EXERCISES WITH HEAVY WEIGHTS.

He gave a demonstration of the method of carrying out these exercises. According to his view of lateral curvature, it was due to general muscular weakness, and habitual faulty position, and hence the whole muscular system should be developed. At each visit the patient is put to his individual limit, and it is found that this usually increases at each visit. He claimed that by this method he had succeeded in curing cases of lateral curvature in which there were bony and ligamentous changes, and marked rotation present. In the milder cases improvement was quite noticeable within two weeks, and a cure would often be effected in three months. He said that out of twenty-one cases treated by him according to this method, nineteen had been cured, and two had been very much improved at the time the treatment had been discontinued. The advantages claimed for the treatment were: (1) The improvement in the general health and in the muscular development; (2) a marked increase in the lung capacity; (3) a slower and more forcible heart action; and (4) that long after the cessation of the treatment, an improvement was noted in the muscular system and in the general health.

DR. S. KETCH of New York, said he agreed with Dr. Weigel, except that he would attribute some benefit to will-power. Regarding Dr. Teschner's paper, he would say that he was not yet convinced that it was necessary, or even advisable, to subject children and adolescents to such a severe course of gymnastics—indeed, he believed that the cases cured by this method could be treated with equal success by other and safer means. It was not difficult to secure an improvement in cases of lateral curvature by correcting the postural curves, but the only test of marked benefit, or of cure, was the amelioration of the

element of rotation. In his opinion, it was important to increase, and to maintain the lateral flexibility of the spine, and hence he would look upon the best method of treating lateral curvature of the spine as that one which combined the use of mild gymnastic exercise and the application of retentive apparatus.

Dr. John Ridlon of Chicago, said that he had tried these heavy exercises on only one patient, a girl of sixteen. This girl became greatly fatigued after making ten or fifteen movements with dumb-bells weighing one and a half pounds, and it was impossible to get her to put a five-pound bell more than five times. As there was no visible improvement in the case after four or five weeks of this exercise, he had abandoned further trial of the method.

The speaker then proceeded to criticise the incomplete and inaccurate photographic records presented by Dr. Teschner, objecting particularly to the absence of photographs of *cured* cases, and also of the best position the patient could be made to assume prior to the treatment. Without these, he said, it was impossible to judge of the merits of the method.

Dr. Reginald H. Sayre of New York, said that he could not accept the statement that development of one part of the muscular system must necessarily be at the expense of the remaining portion. In his opinion, there were many cases of lateral curvature which could not be well treated without mechanical appliances. If it were true that bone changes could be made to disappear by muscular exercise alone, it was certainly a novel and wonderful scientific fact. Until indisputable evidence to this fact was forthcoming, he must be in doubt regarding the kind of cure meant. Nor could he accept the statement that the improvement in muscular development continued after cessation of the exercises, for this was at variance with general principles.

Dr. A. J. Steele of St. Louis, said that he thought there was enough in Dr. Teschner's method to justify him in continuing his work along this line. He could not agree with Dr. Weigel that the spine could not be rendered flexible by means of jackets and similar apparatus.

Dr. Harry M. Sherman of San Francisco, said that while he agreed with those who considered the superincumbent weight the chief etiological factor, he could not but wonder why any bone in the body should be abnormally weak, unless possibly as a result of rickets in early life. He endorsed the use of mirrors as an aid to the proper performance of gymnastic exercises.

Dr. A. E. Hoadley of Chicago, said he considered the prime etiological factor to be "cellular tension," or debility. Such a condition, when present in the intervertebral cartileges, may result in marked shortening of the stature. He had known this to amount to as much as $1\frac{1}{8}$ inches between the time of rising and going to bed at night. When such shortening exceeded half an inch, deformity was invited.

Dr. W. E. Wirt of Cleveland, said that he agreed with Dr. Teschner regarding the increased flexibility of the spine produced by these heavy exercises, but he thought it was a mistake to pin one s faith on one method of treatment exclusively.

Dr. Hanna of Oberlin College, said that in the treatment of cases of lateral curvature she preferred massage to forcible manipulation, together with the use of the hot and cold douche.

Dr. Weigel said that he did not believe that the disadvantages of mechanical supports were as great as had been claimed. He could not believe, as Dr. Teschner had stated, that the muscular strength was increased from visit to visit by the heavy gymnastics.

Dr. Teschner, in closing the discussion, said he admitted the inaccuracies of his records, as of all known methods of recording such cases, but they were the best obtainable under the circumstances. He had made no attempt to pose his patients for their photographs.

Wm. J. Taylor, M.D., of Philadelphia, reported a case of

SPONTANEOUS DISLOCATION OF THE HIP.

which had evidently occurred about six months after a fall. The history clearly indicated that it was not a case in which the dislocation had been produced by the injury, and had been merely overlooked. As the dislocation had existed for fifteen years before coming under his observation, no attempt had been made to dislodge the head of the femur from its position on the dorsum of the ilium.

Several other members reported similar cases.

Joel E. Goldthwait, M.D., of Boston, read a paper upon

THE ANTERIOR TRANSVERSE ARCH OF THE FOOT,

in which he discussed the subject fully. He said that the cases of abnormality of the anterior transverse arch of the foot might be divided into two groups, viz., first, the relaxed form; and second, the rigid type with distinct bony change. The patient stated that the foot was becoming wider, and examination showed a callosity under the head of the second, third, or fourth metatarsal bone. The speaker thought that improper shoeing was largely responsible for the condition. In the treatment of the relaxed cases, it was most important to strengthen the front part of the foot by appropriate balancing exercises, and to relieve the strain on the ligaments and muscles by the application of a snugly fitting bandage, just behind the head of the first metatarsal bone. Immediate relief would follow the application of a pad of felt, so as to make pressure just back of the heads of the second and third metatarsal bones.

Dr. Ketch referred to a case in which the gouty diathesis, rather than bad shoeing, had caused the condition.

Dr. E. H. Bradford said that by means of the roller bandage and felt pads, he had relieved many cases. He had seen no case of true metatarsalgia in which the second metatarsal bone was depressed; they had all been in cases where the trouble was in the fourth metatarsal bone.

Dr. J. E. Moore of Minneapolis, said that he had met with this condition most commonly among nurses. His treatment had been successfully carried out along the lines recommended in the paper.

Dr. Kerr of Washington, D. C., said he had also found metatarsalgia associated with depression of the fourth metatarsal bone, and had relieved the pain and

disability by excision of the metatarsal joint, and sometimes also of the nerve.

THE PRESIDENT called attention to the fact that a proper shoe should be made so that the toes do not point upward, as they did in the ordinary shoe.

DR. GOLDTHWAIT, in closing, said that undoubtedly the chief cause was bad shoeing. In some cases there had been pain at the head of the fourth metatarsal bone, and in others between the second and third metatarsals.

The President's address was on

THE DEFINITION AND SCOPE OF ORTHOPEDIC SURGERY.

DR. WHITMAN suggested the following definition: "Orthopedic surgery is that division of surgery which treats of disabilities and diseases of the locomotive apparatus, and of the prevention and treatment of the deformities of the framework of the body."

INVESTIGATIONS ON FLATFOOT.

E. H. BRADFORD, M.D., of Boston, by means of lantern slides, showed the development and causation of flatfoot. These photographs compared the weak feet of shoe-wearing people with the strong feet of those who were accustomed to go about without shoes.

DR. WHITMAN commented upon the evident advance that had been made in the last decade in the knowledge and therapeutics of this subject.

SECOND DAY, MAY 20TH.

E. H. BRADFORD, M.D., of Boston, presented a paper on

THE TREATMENT OF ABSCESS IN HIGH DORSAL CARIES.

He advocated operation and drainage of the abscess. This operation should be begun by cutting down upon the tip of the transverse process, and resecting a portion of rib, after the manner of an operation for empyema. There was less danger to the heart and large blood-vessels if the incision were made on the right side.

DR. R. H. SAYRE said that Dr. Schafer of Chicago, in some cases of this kind, had passed in a probe and cut down upon it, and had then established through drainage from one side to the other.

DR. SHERMAN said that he had performed the operation in a case in which the abscess had perforated an intercostal space, and produced an accumulation under the skin. The diagnosis was comparatively easy if the way were made plain by the burrowing of the abscess between the ribs.

DR. KETCH referred to a case of very sudden death in a child suffering from disease of the second and third cervical vertebra. Although no autopsy could be obtained, it seemed fairly certain that death had been due to the direct pressure upon the respiratory center.

DR. GOLDTHWAIT said that he had seen the suddenly fatal case which had formed the text for Dr. Bradford's remarks. The cause of the sudden death remained unexplained, for the autopsy showed that the abscess had not ruptured, and there was no evidence of pressure on the spinal cord.

DR. BRADFORD, in closing the discussion, said that where there was disease of the axis and atlas, there was danger of direct pressure upon the respiratory center, but where the disease was lower down, and was associated with suffocative symptoms, it was fair to conclude that an abscess was present. The operation which he had advocated, was certainly a grave one, but it was intended to meet a grave emergency.

SAMUEL KETCH, M.D., read a paper on

SUPPURATION IN JOINT AND SPINAL DISEASE, AND ITS RELATION TO TUBERCULAR MENINGITIS—AN ANALYTICAL STUDY.

DR. J. E. MOORE said he thought it might be safely concluded that the formation of tubercular abscesses did not play a very important part in the development of tubercular meningitis. The evidence in the paper would also seem to point to the fact that operative measures were much less likely to cause tubercular meningitis or general tuberculosis than had been supposed.

DR. A. M. PHELPS said he did not think it was possible for true suppuration to produce a tubercular lesion.

DR. GOLDTHWAIT said that his cases of tubercular meningitis had given only the clinical evidence of this disease, but in every instance the autopsy had disclosed an acute general miliary tuberculosis.

HARRY M. SHERMAN, M.D., of San Francisco, read a paper on

A CLINICAL STUDY OF IODOFORM-GLYCERIN IN TUBERCULOUS OSTEOMYELITIS.

Fifteen of the twenty cases observed were cases of hip disease, two of knee-joint, two of ankle-joint disease, and one of disease of the elbow. In all, 164 injections were made. About half of those were intra-articular, and the other half were intraosseus injections of a ten per cent. solution of iodoform in glycerin. In no case was there any iodoform poisoning, or was the injection the cause of suppuration. The action of the injections was, in most instances, disappointing. In no case was the orthopedic treatment interrupted.

DR. ROSWELL PARK of Buffalo said that he had made an extensive trial of the intra-articular injections of iodoform, but had not seen much benefit from their use. In two cases, coming to excision, the iodoform was found packed into a mass, which acted as a foreign body. He had made some culture experiments with iodoform, and these had demonstrated that the germicidal power of iodoform was very feeble.

DR. J. E. MOORE said that he, too, had met with nothing but disappointment from the iodoform injections, except in the treatment of psoas abscesses. Here, he thought, they had been of some benefit.

DR. HENRY LING TAYLOR of New York said that although iodoform had proved disappointing when injected into diseased joints, he thought a solution of iodoform in ether was a valuable injection for sinuses.

DR. PARK said that as the germicidal action of iodoform was claimed to be due to the liberation of free iodin, he proposed to study the effects of injections of iodin and glycerin.

DR. JOHN RIDLON said that a sharp distinction should be made between cases treated by protective apparatus in conjunction with iodoform injections, and those in which only the injections were used. He had treated about thirty cases by the intra-articular injections. About one-third had showed improvement; another third had remained stationary, and the others appeared to have been made worse by the treatment.

DR. A. M. PHELPS of New York said that he had used the injections of iodoform with negative results. Iodoform and glycerin were useful in tubercular abscesses, partly because of the hygroscopic nature of the glycerin.

JEROME HILTON WATERMAN, M.D., of Buffalo, reported

FURTHER OBSERVATIONS ON THE USE OF HYDROCHLORIC ACID IN BONE NECROSIS OF TUBERCULAR ORIGIN, WITH REPORT OF CASES.

The injections of strong hydrochloric acid were usually made twice a week. His experience was, on the whole, favorable to the method.

DR. W. R. TOWNSEND said that he had observed good results from this treatment, particularly where the necrosis was superficial.

DR. A. E. HOADLEY of Chicago said that the application of a five per cent. solution of hydrochloric acid was sufficient to quickly decalcify the bone, without destroying other tissues.

DR. SHERMAN said that as the chief seat of disease was the granulation tissue in the bone, it would seem to him that the use of the sharp spoon would be more effective.

DR. WATERMAN, in closing, said that the treatment was at times quite slow. He would advise the use of a local anesthetic in conjunction with the acid applications.

WM. E. WIRT, M.D., of Cleveland, read a paper upon

THE USE OF DRY HEAT OF HIGH TEMPERATURE IN THE TREATMENT OF CHRONIC JOINT AFFECTIONS,

and described the apparatus which he employed. It consists of a copper drum, twelve inches long and nine inches in diameter, fitted at each end with a wooden ring and a hood of thick rubber. Having protected the back of the knee with cotton, it is enclosed in the apparatus and heat applied to the outside by means of a Bunsen burner. Most patients would tolerate a temperature between 250 and 300° F., provided three holes were made in the drum to secure proper ventilation, and so keep the air dry. This treatment gives an immediate relief to pain and increases temporarily the mobility of the joint.

BERNARD BARTOW, M.D., of Buffalo, described

DIVISION OF THE HAMSTRING TENDONS BY THE OPEN METHOD FOR CORRECTING MALPOSITION AND SECURING REST IN TUBERCULAR DISEASE OF THE KNEE.

He contended that division of the hamstrings gave quicker relief and secured better rest than did mechanical appliances, and that it cut short the inflammatory process. The operation should be done by open incision.

DR. WIRT thought it was rare that mechanical means would fail to straighten these cases.

DR. R. H. SAYRE said that the operation might be occasionally demanded, but, whenever possible, the straightening should be accomplished by mechanical treatment alone.

DR. B. E. MCKENZIE of Toronto said that he considered the method unjustifiable until after mechanical treatment had failed, and in his experience, mechanical means had never failed under such circumstances. The patients just exhibited should not be allowed to go around without better protection of the joint.

DR. JOHN RIDLON of Chicago was very positive that any joint still diseased could be straightened without operation. He was accustomed to use some form of a Thomas brace. In cases in which the greater part of the rigidity appeared to be due to fibrous adhesions and muscular shortening, without evidence of acute inflammation, he would straighten the limb by manual force, applied under anesthesia.

DR. W. E. WIRT, as an example of what could be accomplished by mechanical means alone, referred to a recent case, which had been pronounced by several surgeons to be one of bony ankylosis, yet he had succeeded, by mechanical measures alone, in straightening the limb in two months.

DR. BARTOW, in closing, said that to insure safety and thoroughness, the operation of dividing the hamstrings should be done through an open incision. In the cases that he had treated by the method described in the paper, he knew of no other alternative than excision; hence he considered the division of the hamstrings perfectly justifiable. The method was only intended as one means of accomplishing an end.

ROYAL WHITMAN, M.D., of New York, read a paper upon

A THEORY OF THE ULTIMATE ETIOLOGY OF DEFORMITY AND ITS PRACTICAL APPLICATION.

He said that in the process of evolution, the erect posture had been comparatively acquired, and that it was an attitude difficult of acquirement and difficult to maintain. The ordinary so-called postural deformities were then explained. The flexion and contraction deformity, he said, was of special interest to the orthopedic surgeon. If one accepted the morphological theory of its etiology, it would be evident that as the erect posture was a newly acquired attitude, so also the uses by the limbs proper to that posture were newly acquired. Complete extension of the limb in the support of this posture required not only the greatest expenditure of nervous energy, but also the greatest strain upon the joint surfaces; and when the ability to assume this attitude became impaired, the affected member became flexed—in other words, it involuntarily assumed an attitude common to the lower or quadripedal form of locomotion. Flexion was an evidence of unbalanced nervous influence and of preponderance of power of the lower or reflex centers. In joint disease the cause was local irritation and consequent muscular spasm; in the second, the inhibitory influence of the higher center was impaired or removed. The erect posture was an evidence of the higher position of man in the scale of evolution. When the controlling force of the higher center was directly or indirectly

impaired, the more difficult and newly acquired attitudes were disused, and the affected part fell backward toward the type from which it had been differentiated.

HARRY M. SHERMAN, M.D., of San Francisco, read a paper entitled

FURTHER OBSERVATIONS ON THE CAUSE OF THE LIMP OF HIP-JOINT DISEASE.

He said that tuberculous bone disease resulted in a wasting of the osseous trabeculæ and the development of an area of structural weakness, usually in the neck of the femur. In hip disease the effort is made to bring the center of gravity of the body as nearly as possible over the head of the femur, so as to relieve the strain upon the structurally weak spot. This theory assumes that there is a "bone sense," comparable to the muscle sense. The speaker then went on to describe by the aid of blackboard diagrams his mechanical theory of the causation of the limp of hip-joint disease. He endeavored to show that the keynote to the subject, from a mechanical point of view, was the fact that the head and neck of the femur constitute a column and bracket, or what is known in mechanics as a "cantilever," and that these anatomical members were, therefore, governed by the same mechanical laws as control the operation of the "cantilever."

DR. WIRT said that he believed the author was in the main correct in his theory, but he would remind him that when running, the femur supports the weight of the body, plus the momentum.

DR. A. M. PHELPS said that he was of the opinion that the capsule of the joint was swollen with tuberculous material, and that as a result, in order to relieve intra-articular tension the patient pulled the limb into a partially flexed position.

DR. BRADFORD said that in some cases the lack of free motion in the joint would account for part of the limp. In cases of cured hip disease, with the limb much adducted, the limp was often due to the effort of the patient to balance himself.

THE PRESIDENT said that the weak point in the author's argument was the assumption of voluntary adaptation of the limb. If this were voluntary, one would certainly not expect it to occur in very early infancy, and yet it was known that the limb assumed such a position in these patients.

DR. WEIGEL said that he would like an explanation of the fact that in the early stage there would be a limp, even though there had been no swelling of the joint. Again, Dr. Judson had shown that patients who had recovered from hip disease, and who still limped, could be trained until the limp was scarcely noticeable.

DR. SHERMAN said that in running the footprints were very nearly in a straight line, thus bringing the point of support nearer to the center. This was not a voluntary, but a reflex act. He believed it was rare for hip joint disease to begin in the capsule. The recovered cases which walk without limp are those in which there is ankylosis between the bones.

A. R. SHANDS, M.D., of Washington, D. C., read a paper on

FEMORAL OSTEOTOMY FOR CORRECTION OF HIP DEFORMITY IN ADULTS, WITH A REPORT OF CASES.

He advocated Gaunt's intra-trochanteric osteotomy. He preferred to do this operation with Gaunt's osteotome having a blade only three-fourths of an inch wide. The only dressing was sterilized gauze retained by adhesive plaster, and a plaster-of-Paris spica applied after a proper position of the limb had been secured.

DR. PHELPS said that he would advise, in a case of double hip-joint disease with ankylosis, the performance of excision, being careful to remove enough bone to prevent ankylosis. He had recently adopted a novel method of securing motion at the joint, viz: cutting through just above the lesser trochanter; bringing down the limb by force; cutting off about three-fourths of an inch of the femur, and then inserting a piece of fascia between the ends of the bones.

DR. SHERMAN said that he would limit this subtrochanteric osteotomy to cases in which there was no motion between the femur and pelvis.

DR. W. R. TOWNSEND referred to several adult cases, coming under his observation, where an excellent result had been obtained by operation for bony ankylosis.

DR. GOLDTHWAIT also cited several adult cases, and remarked that the limb had been put up with ten or fifteen degrees of flexion so as to make it more comfortable for the patient when sitting down.

DR. J. E. MOORE said that while the result was not so likely to be good in cases where there was some motion, he would not confine operation entirely to those cases in which there was complete bony ankylosis.

ARTHUR J. GILLETTE, M.D., of St. Paul, read

A REPORT OF CASES OF OSTEO-SARCOMA OF THE HIP.

He reported three cases illustrating the difficulties in differential diagnosis where there was osteo-sarcoma of the hip. Deformity might not occur for months after the onset of the disease, and there would be in all probability no fixation, very little atrophy, and little or no shortening.

DRS. R. H. SAYRE, SHERMAN, and MOORE, also reported similar cases.

JAMES E. MOORE, M.D., of Minneapolis, read a paper on

TUBERCULOSIS OF THE WRIST AND CARPUS.

He said that wrist-joint disease comprised about five per cent. of all tubercular joint diseases, and occurred most commonly in persons between fifty and sixty years of age. The disease was insiduous in its development, but the diagnosis could be easily made by the swelling, atrophy, flexion, and the peculiar position of the thumbs and fingers. The tendon sheaths were often involved. Children often recover from the joint affection, but rarely live to maturity; in adults it almost invariably ends in phthisis. For children, enforced rest of the joint, by means of plaster-of-Paris dressings, is of service, but for adults it is only applicable to recent cases, and should then be combined with injections of iodoform emulsion. Where there were sinuses and evidence of suppuration, the choice lay between complete excision and amputation. Amputation

was often the most conservative treatment. The author did not favor early excision, because the functional results were bad, and as a life-saving measure it could not compare favorably with amputation. When the disease was well marked and progressing rapidly, when there was well-marked wrist-joint disease with incipient phthisis, and when with the wrist-joint disease there was advanced pulmonary tuberculosis, he would recommend amputation.

Dr. McKenzie said that he had had some very good results in this class of cases from the use of injections of iodoform and glycerin. He had not observed severe reaction following this treatment—indeed, in some instances, the existing pyrexia had been observed to diminish after the injections.

Dr. Sherman commended amputation as the best treatment in cases of severe disease of the wrist.

Dr. Gillette said that some of those who had spoken had implied that these patients suffered much pain. His own impression had always been that wrist-joint disease was associated with very little pain.

Dr. Moore, in closing, said that occasionally pain was prominent. In one case he had done an amputation because of the intense pain, and the result, both as regards prolongation of life and increased comfort, had justified the amputation.

Henry Ling Taylor, M.D., of New York, read a paper on

THE MECHANICAL TREATMENT OF INGROWN TOE-NAIL.

He recommended the following method, modified from that devised by Mr. Masters of England. A flat strip of silver, one-hundreth of an inch thick, and one-eighth of an inch wide, and one inch long, is bent into the shape of a fish-hook. The toe having been cleansed with peroxid of hydrogen, and moistened with a solution of cocain, the hook is inserted under the lateral edge of the nail so that the shank of the hook curves over the side of the toe, and lies close to it. The greater the ulceration, the less the pain in inserting the hook. It is retained in place by adhesive plaster or a bandage. The hook not only protects the flesh from the nail, but it exerts a lifting action on the nail. After a few hours the patient suffers no inconvenience from the hook, and in a few days the swelling subsides, and the granulations become more healthy. It is well to wear the hook for several weeks after the tissues have healed, in order that they may become sufficiently hardened. The method, the speaker said, was applicable to the severest cases.

Third Day, May 21st.

J. C. Schapps, M.D., of Brooklyn, described a

MECHANICAL SUPPORT FOR FLATFOOT.

On hammering out by hand a steel sole to conform to the arch of a well-developed adult foot, it would be observed that the anterior and posterior halves were nearly alike. Having modified the sole-plate so as to make these the same, it was found that the shape resembled that of a portion of the convex surface of a cone, with the apex directed toward the outer side of the sole and the base toward the inner side of the foot. From this plate, plaster casts were made, and these casts served as models from which iron dies were manufactured. With such dies any mechanic could make steel plates, from which soles were easily cut for right or left feet, high or low, large or small feet. A contour of the patient's foot taken on cardboard, was trimmed to fit the sole of the shoe in front, outer side and back, and made wide enough to allow of it coming well up on the inner side of the foot at the arch. This pattern was used to correct the rough outline of the foot taken on the plate itself. The curved line representing the inner edge of the arch of the plate should be located just below the scaphoid and the head of the astragalus. The inner flange of the plate requires careful shaping—it should be nearly vertical as the patient stands on the plate. Having fitted the plate to the foot and to the shoe, it should be covered with vulcanized rubber.

Dr. Schapps also described

SOME APPARATUS FOR THE TREATMENT OF POTT'S DISEASE.

He presented a wheel-cot which he had found useful for the purpose of maintaining uninterrupted recumbency with regulated pressure in Pott's disease. Traction could also be applied. He said that the energy required to hold the spine rigid and the lower limbs in a continuous state of elastic tension to break the shock to the spinal column, exhausted the general and local recuperative forces. It was injurious, in his opinion, to interfere with the respiratory movements of the chest and abdomen. The sternum should be used as a base from which to make forward pressure on a dorsal kyphos. It was also apparent that both the posterior or spinal, and the anterior, or sternal supports of the upper mass should be kept under it, and lateral pressure on the chest avoided. For the treatment of Pott's disease in the upright position, the author used a combination of the Taylor brace posteriorly, and anteriorly a rigid, light support, which made pressure only on the parts which could convey it to the spine without interfering at the same time with respiration.

Le Roy W. Hubbard, M.D., of New York, discussed

THE TREATMENT OF POTT'S PARAPLEGIA.

He reported two cases, and asked if it were possible to reduce the period of paralysis. After reviewing the history of the treatment of this very common complication, and reading replies received from a circular letter that he had sent to the members of the Association, he concluded that if immediate efficient mechanical support were applied to the spine, absolute recumbency enforced until power returned, and a general tonic plan of treatment were carried out, there would be a complete cure in almost every instance, and in the majority, in a short time. Operative treatment was very rarely called for.

Dr. Ketch said that his experience did not show a natural tendency toward recovery in cases in which the paraplegia affected the arms.

Dr. Weigel said that it had been his lot to deal more especially with adult cases, in whom the prognosis was relatively less favorable. He did not think any one could

give even an approximate idea regarding the average duration of Pott's paraplegia.

DR. RIDLON said that his experience had been that the cases in which the sphincters were involved gave the worst prognosis. In one case in which the arms had been affected, recovery had been quite rapid.

A. M. PHELPS, M.D., of New York, described

THE TREATMENT OF CLUBFOOT.

Manipulation and retentive dressings should be begun at the earliest possible moment, and when, after a reasonable time, the progress by this method became very slight, all parts offering resistance to reduction of the deformity should be cut, and the limb put up in a super-corrected position. Out of 343 operations, he had had only five per cent. of relapses, and in the last series—182 cases—there had been no mortality.

REVIEWS.

ELECTRICITY IN ELECTRO-THERAPEUTICS. By EDWIN J. HOUSTON, Ph.D., and A. E. KENNELLY, Sc.D. New York: The W. J. Johnston Co., publishers; 1896.

THIS little book of four hundred pages is one of a series of similar works upon the subject of electricity. The other books of the series are written for the general public, but this one is directed more especially to the medical profession. The work is elementary in its nature, but the subject is made clear, and the book is well illustrated.

DIET FOR INFANTS AND CHILDREN IN HEALTH AND IN DISEASE. By LOUIS STARR, M.D. Philadelphia: W. B. Saunders, publishers.

THIS is a bound volume of prescription blanks for diet. The object of the book is not only to induce more definite principles of diet in the management of sick and healthy children, but also to make it convenient for the physician to practically apply these ideas. The blanks themselves are full of suggestion, and they are bound in form convenient for the physican. The leaves are perforated so that they are easily torn out as prescription blanks to be left with the nurse.

A B C CHEMIST'S VEST-POCKET DIARY FOR 1896. London: Burroughs, Wellcome & Co., publishers.

THIS little book is an embodiment of what its name implies. It contains a variety of pharmaceutical technical information, valuable not only to the pharmacist, but also to the physician.

THE NURSING WORLD BEDSIDE RECORD. For the use of physicians and trained nurses. New York: John Carle & Sons, publishers.

THIS Bedside Record is the outgrowth of a prize competition among readers of the *Nursing World*. It embodies the essential elements of a large number of designs. It is arranged in an attractive manner and printed in colored type, so that the main features of the record will readily catch the eye.

THE NEWER REMEDIES. By VIRGIL COBLENTZ, A.M. Second edition. New York: D. O. Haynes & Co., publishers.

THIS is a convenient inexpensive reference manual for physicians, pharmacists, and students. The constantly increasing number and complexities of new remedies with the scattered condition of the literature upon the subject, render it desirable that the physician should have the facts regarding them in a convenient form. This little book will furnish the latest and most reliable facts regarding these remedies.

HOW TO FEED CHILDREN. A manual for mothers, nurses, and physician. By LOUISE E. HOGAN. 1896. Small octavo, pp. 236. Philadelphia: J. B. Lippincott Co., publishers.

THIS book offers in a practical form, suggestions regarding the application of the principles of dietetics to feeding in the nursery and throughout the period of childhood. The book is practical and attractive, and if free from the error of inculcating over-confidence in the parent or nurse regarding the management of the individual case. The book is full of valuable hints and suggestions that may be of service to any practitioner in the presence of ill-nourished and improperly fed children when presented to him for advice.

FORMULAIRE DES MEDICATIONS NOUVELLES. Par Le DR. H. GILLET. Paris: Bailliere et Fils, publishers.

THERE are to be found in this new Formulary all the recent acquisitions of any value to modern therapeusis. The author has endeavored to discriminate, however, between those that have been established after thorough trial and those which are still in the experimental stage. To those familiar with the French language, the book will be found full of valuable suggestions.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 14, 1896, TO JULY 20, 1896.

The leave of absence on account of disability granted to Major Clarence Ewen, surgeon, is extended one month on account of disability.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 21, 1896, TO JULY 27, 1896.

Captain George E. Bushnell, assistant surgeon, is relieved from duty at Fort Hamilton, N. Y., to take effect upon the expiration of his present leave of absence, and ordered to Fort Assinniboine, Mont., for duty at that station, relieving Captain Peter R. Eagan, assistant surgeon. Captain Eagan, upon being thus relieved, is ordered to Fort Hamilton, N. Y.

Leave of absence for three months, on surgeon's certificate of disability, is granted First Lieutenant Isaac P. Ware, assistant surgeon, Madison Barracks, N. Y.

Leave of absence for one month is hereby granted Captain Paul Clendenin, assistant surgeon, Fort Warren, Mass.

The extension of leave of absence granted Captain George E. Bushnell, assistant surgeon, is further extended one month.

Leave of absence for three months, to take effect on or about August 3, 1896, is granted Captain Edgar A. Mearns, assistant surgeon, Fort Myer, Va.

EARLY DIAGNOSIS OF MALIGNANT DISEASE OF THE UTERUS.

BY WALTER B. CHASE, M.D.,
OF BROOKLYN, N. Y.;
GYNECOLOGIST TO BUSHWICK HOSPITAL.

THERE are no more melancholy pages in the annals of human suffering than those which relate to the ravages of malignant disease of the uterus. To the gynecologist, the power of early diagnosis is as essential to the highest success in its management, as a sensitive conscience is to the moralist or the compass to the mariner. No matter how broad the culture, how consummate the skill, how exact the technic, or how perfect the mastery of the subject in other particulars, a lack of corresponding acquirement in ability to make the earliest possible diagnosis, may be fatal to the safety of the patient.

Notwithstanding the rapid advance in surgical pathology, and the aid clinical observation confers, the most expert diagnostician is painfully conscious of the limitation of his knowledge in the early stages of this fatal disease, and the meager data upon which he must formulate his deductions. While the evils which attend this very limitation of knowledge are a great embarrassment to the diagnostician, they bear with far greater severity on the unfortunate woman whose safety may hang on his ability to make an early and correct diagnosis. This power of early diagnosis as to benignancy or malignancy in uterine disease, is the ability to make plain the dim inscription on the signboard at the divergence of the two ways, one leading to hope, the other pointing to despair. Every dictate of reason, every consideration of safety, and every philanthropic impulse, demands the most careful scrutiny of every condition and detail which will aid in reaching correct conclusions. Nowhere in the domain of surgical procedure is avoidable delay more to be deprecated, and nowhere are the consequences more cruelly relentless. The diagnosis must rest on the information which pathology and clinical experience offers, and their combined wisdom must be invoked to yield the most trustworthy evidence.

Various answers have been given to the interrogatory, What is cancer? A simple and rational answer is found in the statement that it consists of the presence of cells out of time and place. It is the presence and growth of epithelial cells, having within themselves an inherent tendency to rapid reproduction with abnormally low powers of resistance. The etiology of malignant disease is a matter of great interest, but the scope and purpose of this paper is so modified by necessary limitation, that this, with certain other aspects of the case, can be but briefly referred to. This limitation, to a large degree, applies to the minute histological study of cancer. Formerly it was held that the local manifestation of malignant disease was the secondary manifestation of a general systemic condition, but the development of cellular pathology has swept away any such hypothesis. The cells of cancer are heterogeneous to the particular structures in which they are found. The theory that they are congenital, finds able supporters, while others hold that various accidental causes are responsible for their presence, which includes inflammatory and degenerative changes. Different authors and writers have adopted various classifications of malignant disease, but one based on the pathological condition, rather than the clinical varieties, commends itself both for simplicity and accuracy. Such a natural classification of uterine cancer is found in the three pathological varieties, viz: adenoma, sarcoma, and carcinoma.

In point of manifestation, carcinoma—the epithelial type—is most frequent and most malignant; next in order of frequency is adenoma (not always malignant), the glandular type. Sarcoma ranks next, and while rare, possesses a high grade of malignancy.

The etiology of cancer, though a problem of importance, has not been authoritatively settled. Among the causative and predisposing factors, may be mentioned age, heredity, frequent gestation, and degenerative and hyperplastic changes. Skene, after analyzing many thousand cases, found an inherited taint in thirteen per cent. Comparative views of different writers give authority to the belief, that in quite a percentage of cases the line of progenitors for one or two generations had been, to a certain extent, victims of malignant disease. Evidently the relation be-

tween the number of children born and the frequency of uterine cancer is more than accidental. Traumatism as an etiological factor has not, I am fully assured, been accorded its proper place as an exciting cause. As substantiating this view, I have, after many years' observation, met with only a single case of cancer of the cervix in a woman who had not borne children, or who had at least not been pregnant; while cancer of the cervix and corpus has been of frequent occurrence in child-bearing women. Clinical experience gives ample proof that a close relation exists between laceration of the cervix and cancer of the cervix. Every woman who is known to have an unrepaired cervical laceration should either have the laceration repaired or be kept under regular observation until a period some years subsequent to the menopause, as a wise and reasonable precaution. The remarks of Goodell that "cancer of the body of the womb is a disease more of old maids and sterile wives, and that on the other hand, cancer of the cervix is almost always found in women who have borne children," is not without significance.

The rôle which syphilis, in its more remote effects, plays in the production of malignant disease, is as yet undetermined, but there is reason to believe it is not in certain cases without influence. The relation which undue, frequently repeated, and long continued irritation of uterine structure may bear to uterine cancer, is difficult of determination, but that it may be an important factor seems more than probable. The frequent development of epithelioma on the lips of smokers, and sarcoma resulting from contusions, lends plausibility to the theory.

Malignant disease of the cervix presents itself under two distinct varieties: one squamous-celled epithelioma (carcinoma) springing from the vaginal surface, and columnar-celled arising from the cervical glands or the cervical epithelium. The first variety show a tendency to outgrowing vegetations, involving the vaginal wall, rather than the connective tissue or substance of the cervix; while the second variety develops in the deeper structures of the cervix as a small nodule, and has a tendency to invade the corpus, and later the broad ligament. Being concealed from view, it covertly accomplishes its destructive course, and is liable to elude observation until its ravages are wholly beyond control.

Sarcoma of the corpus is rare, and that of the cervix still more infrequent. Great rapidity of growth and great malignancy are the common characteristics of sarcoma uteri. The rapidity of the development of sarcoma is sometimes a mark of malignancy almost pathognomonic. A case which strikingly illustrated this feature of sarcoma recently came under my observation in a young woman, twenty-four years of age, which ran a fatal course in a little less than four months. It was of the diffused type, preceded for some period of time by symptoms of menorrhagia, developing itself in the broad ligament, simulating pelvic peritonitis, which made diagnosis impossible until the period was reached when it became inoperable; and then with galloping speed involved the entire corpus and left ovary.

In development carcinoma falls short of any definite glandular formation, while adenoma is distinctively such. As to frequency of malignant disease of the cervix, that of the columnar-celled type predominates over the epithelial, while in the corpus, adenoma is the rule. In carcinoma of the corpus the point of development arises in the glands as papillary proliferations into the cavity or into the uterine wall. Virchow describes three varieties of sarcoma, the round-celled, the spindle-celled, and myxo-sarcoma. They are regarded as equally malignant, equally infectious, and in the main their symptoms are identical, or at least similar. Sänger describes another variety known as *sarcoma deciduo-cellulare*, arising from decidual remains succeeding pregnancy, as the protoplasmic bodies closely resemble decidual formations.

Thornton, in a recent article in the *Lancet*, justly emphasizes the fact that any menstrual departure from the normal, no matter how trivial, is sufficient ground on which to insist on a thorough local examination. The causes which lead to excessive menstruation and uterine hemorrhage are so numerous and diversified that no effort will be made to differentiate them, except in so far as they relate to malignancy, and here only partially. Any escape of blood from the vagina at a period subsequent to the menopause, is a matter of deep significance, and, except in rare cases, is the concomitant of malignant disease. Any failure to accord it full significance and searching scrutiny, is, on the part of the general practitioner or gynecologist, not only culpable but little less than criminal. I have personally met with but few cases in which this symptom did not portend malignancy. The question whether menstrual excess or intramenstrual hemorrhage is due to systemic or local disease is of vital and far-reaching significance; and if local, whether the disease is malignant or suspicion points in that direction. The unfortunate fact connected with so many

cases of uterine cancer is that they come under observation so late as to be inoperable.

It is to be noticed that carcinoma of the cervix is more frequently found among the poorer classes, and is relatively a disease of mature life, most often found between thirty and sixty years. It was formerly believed that carcinoma of the corpus was extraordinarily infrequent, but improved methods of diagnosis and further observation disproves the assertion. The hemorrhage in cervical cancer may at first, in young women, retain the menstrual type and later on become irregular, while, after the menopause, it is atypical. In the very early stage of ulceration there may be entire absence of the putrefactive stench which is so often a characteristic feature. Such a case has just come under my observation, in a young and typical epithelioma of the cervix, in a woman sixty-three years of age. The duration of the disease varies greatly. Its progress may be slow or rapid. It has been known to terminate fatally in a few weeks after its perceptible beginning, or the patient may linger for a period of four or five years, the average being less than two years. It is a singular fact that women with carcinoma are found somewhat frequently to have increased sexual desire. The slight bleeding, incident to digital examination, should excite suspicion, and the cause determined, whether due to some form of erosion so frequently present on the cervix, whether the result of laceration and eversion so common in women who have borne children, or to graver causes. If the cervix is the seat of malignant disease, sight and touch will greatly aid in differentiation. In the early stage there is usually increase, perhaps slight, but appreciable, of the new structure with a tendency to invade contiguous tissue. The first change observable is enlargement and hardness of red nodules, which bleed easily and break down on touch as the disease progresses, the tendency to disintegration increases, and is attended with sero-purulent discharge and blood. The hard rim of the excavation, the crater-like depression, its tendency to bleed, are the unmistakable evidences of cancer. If these appearances are not already present in a degree sufficient to warrant an opinion, the case should be carefully watched, and gentle treatment applied to see whether the diseased surfaces heal. If of benign origin, the erosion or ulcer is likely to heal; if malignant, healing will not follow. The form of erosion in cancer of the cervix differs from follicular erosion, the edges being indurated and elevated. The papillary projections in cancer break down when scraped with the finger-nail much more readily than the benign variety. Another distinction to be made between cancer and cervical endometritis, in its clinical history, is that in cancer the discharge has lost its mucous consistency, as mentioned by Boldt. When the disease originates in the cervical mucosa, or in the deeper cervical structures, the symmetrical or asymmetrical condition of the portio vaginalis should be closely observed. In the squamous-celled variety of cervical carcinoma the posterior lip is the point most frequently attacked.

Dr. John Byrne, whose large observation and experience in the treatment of uterine cancer, and whose opinion is entitled to great weight, says: "Regarding physical examination alone, without allusion to history, the existence or absence of hemorrhage, pain, etc. (the latter which has no special significance), that in women long past the menopause the portio will be found smaller, less projecting, and presenting a somewhat shriveled appearance, particularly around the os; whereas, in earlier life, say from thirty to forty, I have usually observed the portio longer than normal, *but symmetrically so.* When the diseased structures of the cervix are invaded, whether primarily or by extension, the change in form will rarely be found symmetrical, but one or the other lip enlarged and indurated and probably abraded."

If, as is sometimes true in the doubtful cases, the most careful clinical study is insufficient to determine the nature of the disease, diagnosis may be arrived at by detaching a small portion of the structure for microscopical examination. When this step is ventured on, before the ulcerative process has appeared, every preparation should be made for prompt operation if admissible, as soon as the histological study is completed, for such exposure adds vastly to the risk of more rapid spread of the disease. If the disease attacks the corpus, its usual initial point is on the free surface of the endometrium, in which event the cervix may be dilated, and the finger introduced for purposes of exploration. By this method areas of inflammatory enlargement, hypertrophy, and ulceration may be accurately located, and, in certain cases, serve as guides to curettage. Sometimes an examination of the *debris* spontaneously discharged or removed by the curette, may contain sufficient tissue on which to predicate the nature of the malady, and it is here that the skill of the pathologist finds a most attractive field for investigation. The causes for uterine hemorrhage are so frequently associated with inflammatory and degenerative changes of the endometrium, oftentimes benign, that the findings of

curettage are often of the highest value, not only for diagnostic purposes but for the selection of curative measures. If the disease has not progressed to a well-marked ulcerative stage and the menorrhagia occurs, positive evidence of malignancy, independent of other distinctive symptoms, may not be present until a second or third curettage. If the histological examination warrants the conclusion of malignancy the indications are plain. If otherwise, and hemorrhage continues, the employment of radical measures without positive proof of malignancy may be justified. There seems to be a growing consensus of opinion that menorrhagia of considerable duration not relieved by thorough curetting thrice repeated, possesses the essentials of malignancy and should be treated accordingly.

There is a form of adenoma uteri,[1] very little mentioned in literature, concerning which I have been able to find nothing in any English or American text-book or medical journal. I am indebted to the courtesy of my friend, Dr. J. M. Van Cott, Jr., Pathologist to the Brooklyn Gynecological Society, for the following brief résumé of the subject:[2] "It is a lesion of the corporeal portion of the endometrium, which consists of a chronic persistent hyperplasia of the endometrium, with adenomatous degeneration and progressive growth of the endometrium between the muscular bundles of the metrium proper. This produces a globular enlargement of the corpus uteri with atrophy of the muscular tissues and recurrent hemorrhage, which is severe and does not yield to curettage or any other form of treatment short of hysterectomy. It may occur at any period after the age of puberty; but is, perhaps, most common after the menopause. The diagnosis of this lesion is often surrounded with great difficulty, and can only be established by means of conjoined microscopic examination of accurately cut and prepared sections, in collodion or paraffin, and the clinical history of the case extending over a period covering several hemorrhages, recurring after thorough curettage. The diagnosis of this disease being positively assured, hysterectomy alone can afford permanent relief."

Skene teaches that there is a tendency in cases of benign adenoma of the endometrium, following curettage in from six months to two years, to be succeeded by epithelioma, and suggests the propriety of hysterectomy according to the pathological findings. Martin mentions the occurrence of the same procession of symptoms, and recommends that where a single curettage is not attended by cure, hysterectomy should be done. Conditions analogous to these are not infrequently met with by one having much to do with the diseases of women. They are entitled to the most considerate and discriminating investigation, as the personal safety and future welfare of the patient depends on the skill and courage of the one to whom is entrusted such sacred prerogatives. This conclusion involves a discrimination from uterine hemorrhage due to benign neoplasms, such as submucous fibromata, myomata, or polypus, or of benign degeneration of the uterine mucosa, and the state of chronic ovaritis and some forms of metritis. An unusual form of inversion of the uterus, associated with great hyperplasia of its walls, in fleshy women with very thick and fat abdominal parietes, in which the tumor fills the pelvis as completely as the head of a child in a second stage of labor when associated with violent hemorrhage and profuse watery discharge and a thickened and abraded surface, is not, on first observation, so easy of determination. The presence or absence of offensive odor of the vaginal discharge in suspected cancer is a symptom of great significance. An ichorous, foul-smelling discharge, more or less mingled with blood, is, with some exceptions hereafter noted, almost pathognomonic of cancer. If associated with these symptoms there are those of pain and cachexia, the diagnosis is practically established. It should, however, be remembered that anemia, as expressed by pallor, is not cachexia, and is a usual concomitant of exsanguination in conditions where there is absence of malignancy. On the other hand, absence of pain as a single symptom by no means excludes cancer, for malignant disease may be far advanced, and yet painless. Exceptions are found in cases of long retained and decomposing placenta following miscarriage or premature labor, ulcerations found at seat of such placental implantation, and in some forms of neglected syphilitic ulceration. Another condition I have seen mistaken for cancer of the corpus in women ten or fifteen years beyond the menopause, associated with purulent and highly offensive discharges and great pallor, is that of small, sloughing submucous intrauterine fibroids, in which prompt recovery succeeded their removal. Diagnosis under such conditions would be facilitated and probably assured by careful microscopic examination of the discharges.

Doubtless these fibroids were present before the menopause, and had diminished in size *para passu* with the uterus while it was undergoing connec-

[2] *Brooklyn Med. Jour.*, June, 1896.

tive tissue metamorphosis, by which the blood-supply was cut off and disintegration followed. There is a form of erosion and ulceration due to pressure of pessaries and the attrition incident to procidentia and purulent discharges of venereal origin, which must be distinguished from cancer. There are some points in the clinical history of cancer not alluded to, which should not be lost sight of. Perhaps the most important is the method of growth and dissemination of the cancer-cell. The spread of carcinoma and adenoma is through the lymphatics, that of sarcoma by contiguity of tissue and blood-currents. For this reason enlargement of the lymphatic glands would not obtain in the clinical history of sarcoma. Fixation of the uterus as an incident of cancer is worthy of careful study. Unless a clear history of the case from some authoritative source excludes previous pelvic inflammation, there may arise a nice point of distinction, whether the fixation is due to former adhesion or to extension of malignant infiltration. Careful study of the point of maximum fixation and its proximity to the seat of the disease, aided by thorough bimanual palpation, or the admirable method of diagnostic palpation so graphically described by Edebohls, will usually dissipate the doubt. Again, cancer is not to be confounded with constitutional impairment and offensive vaginal discharge found in fistulous openings into the vagina or uterus.

In malignant disease of the corpus not involving the cavity, early differentiation is a matter of great difficulty. Fortunately, however, it is a matter of infrequent occurrence. Absence of uterine discharge would not exclude its presence, as is true in the case of diffused sarcoma of the body. The presence of cachexia in suspected cases is a symptom of such recognized value as to require no comment. Conditions may exist in these or analogous cases where exploratory section, either vaginal or abdominal, is not only justifiable, but necessary, for diagnostic purposes, as in suspected cancer of the corpus and in fixation due to supposed previous adhesion.

In all that has been said of the varieties of uterine cancer, it should be remarked that the symptoms are essentially a unit, and do not vitally differ in the various varieties. Failure to find conclusive evidence in a given specimen of suspected structure would not alone be sufficient to exclude the diagnosis of cancer. Again, it should be borne in mind that the histological study of different mountings of the same specimen by two equally expert pathologists, in which the findings differed radically, one showing malignancy and the other absence of it, would not disprove a diagnosis of malignancy. In other words, negative testimony, set over against positive proof, is without weight, and valueless.

Finally, the intrinsic value, for diagnostic purposes, of the information derived from expert microscopical examination of diseased structure is equal to that of every other consideration mentioned, providing, however, the conditions are favorable for such investigation. Both time and space forbid entering on the differential diagnosis of these growths from the histological standpoint. Suffice it to say, however, that the evidence it presents is authoritative and final.

ON THE TREATMENT OF BIRTHMARKS.

By ELLICE M. ALGER, M.D.,
of New York;
Instructor in Dermatology in the New York Polyclinic; Attending Physician Demilt Dispensary.

The comparative frequency with which one sees upon the street or in private practice most distressing cases of birthmarks, must have been noticed by every observant physician.

And the fact that beautiful girls are allowed to pass through life with a crimson stain upon the forehead, or a yellow mark upon the cheek, would argue that many family physicians are entirely unaware of the ease with which many of these hideous disfigurements can be obliterated. They are, as a rule, present at birth, though they may not be noticed till some time after, and are generally ascribed by the laity to some previous impression made upon the mind of the mother. This theory has been much ridiculed, but the frequency with which cases, apparently substantiating it, are met with should make us cautious in our disbelief. Almost every person has a birthmark of some kind somewhere.

One of the commonest types is that called the nevus araneus, or spider nevus, from its resemblance to the small red garden spider.

It consists of a central dilated capillary, with a few little radiating capillaries, and occurs chiefly on the head and face, a favorite location being at the junction of the nose and inner canthus of the eye. Another anomaly of circulation gives the port-wine nevus (nevus flammus), which may occur upon any part of the body, but is especially frequent about the head and neck. They may be of the size of a dime, or may cover half the face, of any shape, flat or raised, rough or smooth. In color they vary from a bright red to a steel blue, depending in part on the condition of the blood, whether arterial or venous, but more on the depth of the vessels beneath the skin.

They may appear at birth, or may not be noticed for months; they may remain stationary in size or may possibly disappear spontaneously, while in a certain proportion of cases they steadily increase. All are marked by a tendency to blanch on pressure. In this form there is a simple increase in the size and number of the capillaries. Very different is the structure of the angiomatous nevi, in which there is an increase of connective tissue, while the blood is poured directly from the arterioles into the enlarged veins and sinuses without the intervention of capillaries. The whole structure being somewhat analogous to the corpus cavernosum, becoming erectile when irritated, and at times bleeding very easily. These are especially prone to occur about the mucous orifices, especially the mouth and vagina, and are by all means the most difficult to treat successfully. Entirely different in character and structure, but hardly less disfiguring, are the pigmented birthmarks. The simplest of these consists of a simple increase in the coloring matter of the skin, and is not raised above the surface, appearing as a brown mark, technically known as nevus spilus. Generally there is associated with this a decided hypertrophy of the connective tissue elements, causing a raised brown mark, generally small. The color varies from lemon to almost black; the surface may be smooth, or it may be rough enough to resemble a wart. The glandular and pilary elements in the skin may be atrophied or there may be a luxuriant growth of hair, darker in color than that of the rest of the body. This last form is generally called nevus pilosus, while if it contains an excessive amount of fatty matter it is called nevus lipomatodes. These pigment moles are much more likely to be multiple than the vascular ones. There are, of course, other varieties of moles, which are at times congenital, but those described affect most patients' peace of mind, by reason of the disfigurement they cause.

They have been treated by caustics and acids, by the actual cautery, by pressure, by ligature, and by vaccination. The nevus araneus is very easily destroyed. A needle may be dipped in carbolic acid and plunged into the central capillary, thus destroying the whole mark in a very few seconds. A very hot needle is equally effective, but these methods of procedure are objectionable where larger growths are concerned. They require great fortitude on the part of the patient, or the use of an anesthetic, and they give considerable pain afterward, while the destruction of tissue cannot be very well controlled. This is a very serious drawback, for we depend for our result upon the substitution of a scar for the mark, and the lighter and thinner the scar, the better the cosmetic effect. For these reasons, the methods outlined above should never be employed about the uncovered parts of the body. The use of freshly prepared ethylate of sodium has been very highly recommended in vascular nevi that are not too large and deeply situated. It is rather painful, but after one or two applications, a thin crust forms which falls off in a few days, leaving a fairly thin scar. But unless the solution is freshly and carefully prepared, it is in effect an aqueous solution of caustic soda.

All things considered, the use of electrolysis is by far the most satisfactory means of treatment, but in order to secure good results it is necessary to have a good idea of the physical and chemical properties of the current. The appliances necessary consist of a galvanic battery of at least ten cells, or some means of regulating the street current, conducting cords, sponge electrodes, needle-holder, needles, etc. A milliamperemeter is not necessary, but it is an assistance to good work. The cells should be connected zinc to carbon. The needle-holder is better without the spring for breaking the current which is so generally provided, the needle may be varied in size according to the character of the work, from that of the very finest jeweler's needles to the broad flat surgical ones.

The sponge or punk electrode, attached to the positive pole, thoroughly moistened with saline solution, can be continuously applied to the skin, regulating the current through a rheostat, but the best way is to have the patient hold the sponge and complete the circuit by pressing it against some convenient part of his body. It is less painful to break the current at the positive pole, and the patient is able to regulate the current in part by increasing or decreasing the pressure. The needle attached to the negative pole should be introduced at the margin of the growth, either perpendicularly to the surface of the skin, or in a slanting direction, according to the size and depth of the nevus, and a current of from one to three milliamperes used according to the patient's fortitude. There is at once evolved at the negative pole about the needle, hydrogen gas, which can be seen bubbling up, and a caustic alkali, which destroys a certain amount of tissue in proportion to the strength of the current and the depth to which the needle has penetrated. No arbitrary rule can, therefore, be laid down as to the time, which is dictated entirely by experience. If it is left too long, too deep a scar results; if not

long enough, no appreciable effect is produced. The proximity of the insertions must be governed by the effect desired, which is to combine the white of the scar-tissue with the red of the nevus, so as to produce a general effect as much like the rest of the skin as possible. The punctures should not be closer together than a sixteenth of an inch. If the mark is large, work can be facilitated by using a group of needles.

In the large angiomatous nevi, it is much harder to get a perfect cosmetic effect, for the scarring is apt to be deeper and more irregular, and on the whole, a different procedure is advisable.

The negative pole should be attached to the sponge this time, and we substitute for the steel needle a coarser one, of either copper, zinc, or silver, attached to the positive pole. This should be introduced deeply into the mass, and a current of from three to five milliamperes used, as it is less painful than negative electrolysis. About the needle are evolved oxygen, which can be seen bubbling up, chlorin and an acid, which are destructive to the tissues. This effect, however, is less active at the positive than at the negative pole.

The peculiar value of this method is, however, that in addition to the local destruction of tissue, the needle is rapidly oxidized and decomposed, and there is deposited an oxychlorid of copper or zinc, which is carried by the cataphoretic property of the current and diffused, coagulating the blood in the vessels. The needle is roughened after a short contact just as a nail is rusted, and sticks closely to the puncture, but comes away easily enough by reversing the poles of the battery a few seconds. But in the great majority of cases of angiomatous nevi, it is not safe to make definite promises of a good result. The pigmented moles are best treated by negative electrolysis, and as the pigment is not deposited very deeply beneath the surface, the needle need not be introduced so deeply, better results being obtained by passing it just beneath the surface from one side of the mole to the other, repeating the process according to the size of the mark.

In all these cases there will follow for several hours some signs of cutaneous inflammation, which can best be treated by means of hot water. No great change in the appearance of the growth must be looked for at the time, but in the course of a few days a crust will form and come away, leaving in its place a slight scar, which constantly tends to become thinner and fainter. When the pigmented moles have hairs in them, they must be destroyed by a fine needle attached to the negative pole, introduced into the hair follicle until the hair comes out with very slight traction. This is generally much more painful, for while the moles themselves are not at all sensitive, the hair follicles are, and a correspondingly weak current must be used.

CLINICAL LECTURE.

THE USE OF BENZO-NAPHTOL WITH BISMUTH SALICYLATE IN THE TREATMENT OF THE SUMMER DIARRHEAS OF YOUNG CHILDREN.[1]

By SOLOMON SOLIS-COHEN, A.M., M.D.,
OF PHILADELPHIA;
PROFESSOR OF CLINICAL MEDICINE AND THERAPEUTICS IN THE PHILADELPHIA POLYCLINIC; PHYSICIAN TO THE PHILADELPHIA HOSPITAL, ETC.

Although not a professed pediatrist, it has fallen to my lot to see a sufficient number of cases of various forms of intestinal disturbance in children, especially during the hot weather, to have warranted the formation of an opinion concerning the proper method of treatment to be pursued in such cases. It has appeared, in so far as personal experience is concerned, that many of the nosologic divisions and refinements of diagnosis, which find place in the text-books and monographs, are of little practical account at the bedside. Whether the inflammation in a given case be confined to the colon or involve the ilium, whether it be intestinal only, or gastric as well, has seemed to be a matter of entirely minor importance. Indeed, the use of nomenclature involving the idea that the local inflammation was the important pathologic factor in the complexus of morbid phenomena presented, has seemed to be a survival of the errors impressed upon the profession by Broussais and his school. It is undoubtedly true that local morbid processes are present and of importance, and that if these proceed unchecked, inflammation so serious as to become in itself a source of danger may be produced; yet in the majority of cases in which infants or children present symptoms of disturbance of the alimentary canal, the local phenomena are those of irritation rather than of structural change, and the systemic phenomena those of intoxication chiefly. Thus, the apparent site of the local phenomena may change in the course of the case as the irritating materials change their position, and the same case successively appear to be one of gastritis, of enteritis, of ileocolitis, and of colitis, if we are to hold to the received nomenclature. For this reason the old terms cholera-infantum and summer diarrhea seem to me more expressive and less erroneously exclusive than the others mentioned; the former term being applicable to cases of severity, and usually attended with vomiting as well as purging, the latter to those of milder character in which purging is the main feature. But the question of nomenclature is of importance only as a name serves to recall a defined group of morbid associations; and the prerequisite to successful treatment of the classes of cases referred to is as clear an idea as possible of their origin, mechanism, and course.

[1] Therapeutic Talk, delivered at the Philadelphia Polyclinic Hospital.

The causation seems to be complex, involving nervous influence, mechanical irritation, bacterial infection, toxin absorption. The nervous influence depends on temperature; that is to say, the local circulation is injuriously affected, probably partially paralyzed, either by the heat of the weather, or by the injudicious administration of cold, often ice-cold water.

There is no doubt that the judicious use of cool water, internally and externally, aids in preserving the health of infants during the heated term, but it is a matter of common observation to find painful or spasmodic disorders of the alimentary canal caused by the sudden chilling due to the rapid ingestion of ice-water both among children and adults. Sucklings escape this danger, at times, because they are less inclined than older children or adults to "gulp" down a large quantity of cold fluid at a single draught. If cool water rather than ice-cold water be employed, and a small quantity held within the mouth, cooling its mucous membranes and at the same time being raised more nearly to body-heat before entering the stomach, this particular etiologic factor may be eliminated.

Irritation may be due to the mechanic or chemic qualities of the food ingested or to its contamination with microörganisms. Even when the food itself is harmless under ordinary circumstances, it may irritate a stomach or bowel depressed in function by the excessive temperature, or chilled by iced water. Want of scrupulous cleanliness as to bottles and nipples, cups and spoons, is frequently found to be a cause of septic contamination of food, even among families in which it would not be suspected; a fact that excuses the mention of a factor so well recognized. Milk or meat juice may contain noxious products of decomposition or bacterial action, even when there is no evidence of this given to the senses, and despite the fact that the milk has been pasteurized or sterilized. So too, with artificial foods, which, though perhaps sterile when put up, easily become unfit for use by exposure to the air and to moisture after the packages are opened. In connection with the latter preparations still another source of contamination exists, namely, the use of unboiled water in cities which, like Philadelphia, are supplied with diluted but unfiltered sewage for drinking purposes.

Whatever then, the character of the food that is being given to an infant or child presenting symptoms of gastro-intestinal disturbance, save only in the case of infants suckled by healthy mothers or wet-nurses, it should be changed immediately; and this, whether or not the exact source or nature of its unfitness can be discovered. The sickness of the child is a demonstration of such unfitness by *experimentum crucis*. No other is needed.

The alimentary canal should at once be cleansed of irritating and toxic matters. If this can be accomplished by the administration of a mild laxative, calomel in small doses, or castor oil and aromatic sirup of rhubarb, without lavage, it is better to avoid the passage of a stomach tube. I say this after sufficient personal experience with both methods. If, however, vomiting is marked, action urgent, and medication ineffective, the stomach should be washed with warm water (100° F.) and sodium borate or sodium bicarbonate, one dram to the pint. If desired, a bismuth mixture may be introduced through the tube before the latter is withdrawn. I have had no experience with this procedure. To cleanse the bowel a high enema of warmed normal salt solution is usually the best method. When, however, the laxative has acted promptly and satisfactorily, this may often be dispensed with. As a rule, I prefer, over mercurials, a mixture of equal parts of castor oil and aromatic sirup of rhubarb, sometimes with the addition of a few drops of paregoric. It is not unpleasant to take, is mild in action, and there is a desirable astringent after-effect. The dose should be in accordance with the age of the child; an infant of six months will take about a teaspoonful of the mixture, repeated if need be, once or twice, at intervals of one or two hours; a child of two or three years will take about a dessertspoonful; a child of seven to ten years, a tablespoonful.

After the bowel, and, if need be, the stomach, have been cleansed, I have found nothing more satisfactory to soothe and disinfect the alimentary canal than a powder, the use of which I first reported in THE MEDICAL NEWS for July 28, 1894, p. 97.

My own experience has been confirmed by that of many friends who have from time to time communicated with me. It consists of benzo-naphtol (benzoyl-beta-naphtol) and bismuth salicylate, usually in equal parts, with or without the addition of Dover's powder. The dose is regulated rather by the size of the powder, that is, the child's ability to swallow it, than by the quantity of active drug, except as regards the opium, which varies with the age of the child and the severity of the case. A child of six months can usually swallow three grains of the powder, say one and a half grains each of benzo-naphtol and bismuth salicylate, and some can take much more. When a sufficient quantity to produce the desired effect cannot otherwise be given, a dose of even five grains of each constituent may be divided into manageable portions (perhaps a little sugar of milk added, though this is rarely necessary) and given at intervals of ten minutes, more or less. The dose for an adult is about five grains each of bismuth salicylate, benzo-naphtol, and Dover's powder. It is the combination, not any one constituent that is effective. The intervals between doses vary from two to four hours, at first, and are prolonged afterward in accordance with the improvement in symptoms. Since resorting to this treatment I have not had to use chalk-mixture, or soda and rhubarb, or other mixtures of that kind.

It is important, however, to stop milk-feeding during the active treatment. Barley-water in small quantities is the best diet for two or three days. After that, freshly prepared meat juice, an unobjectionable proprietary food, Pasteurized milk, or even boiled milk may be used, under proper precautions as to cleanliness, physical and chemical. I have found the intermission of milk diet (or other food) the most difficult matter to enforce, not only upon mothers, but often in consultation cases upon the attending physician. Yet it is a factor of the highest importance in treatment. Children will do much better with no food whatever, than if food which readily decomposes or yields toxins is placed in an alimentary tract where all the conditions are favorable to such transformation.

The usefulness of the medication proposed seems to be that it assists in the return to normal conditions, so that food may again be safely taken.

Another error, against which it is necessary to utter a word of warning, is the practice of administering an opiate or an astringent, such as logwood, kino, or tannic acid, before the alimentary tract has been cleansed of offending, irritating, poisonous materials. The frequent stools are evidences of nature's efforts to get rid of these matters, and the physician who injudiciously locks them up in the bowel by his drugs aids the disease rather than the patient.

To sum up then, the proper line of treatment is rest, fresh air, cool bathing or sponging, cleansing of the alimentary tract, intermission of food liable to decomposition or fermentation, the administration of cool water and barley-water in small quantities, the water having been boiled and filtered when necessary, and medicinally the use of a sedative and antiseptic mixture, for which purpose benzo-naphtol and bismuth salicylate, with or without opium, are of great use. In cases of severity, approaching collapse, hot bathing, external application of heat, and the use of strychnin in appropriate doses, may be additionally necessary.

I have as yet said nothing concerning alcohol. It is often of use, in small quantities, and may well be given with the barley water; but there are many cases in which it is unnecessary, and the decision is a matter of good judgment in the individual case. I, at least, can formulate no general rule.

CLINICAL MEMORANDA.

A CASE OF TRAUMATIC RUPTURE OF UTERUS, WITH LACERATION AND STRANGULATION OF SMALL INTESTINES; OPERATION; RECOVERY.

By C. S. VAN RIPER, M.D.,
OF PATERSON, N. J.

THE following case is reported with a two-fold object: Because it is, in its nature, circumstance, and result, unique; and because it may serve as a warning to young practitioners of the danger attendant upon the rash use of "Goodell's Cervical Dilator" in the unimpregnated uterus.

On June 9, 1894, in the evening, I was consulted by a physician, who informed me that he had a patient, thirty years of age, multipara, her youngest child being twelve months old. She had been suffering with slight vaginal hemorrhage for the previous month, but gave no history of the usual symptoms of tubal pregnancy. He, supposing it to be due to polypoid degeneration of the endometrium, had an assistant etherize her, with the object of performing a curettage. The patient being under ether and placed in position, he introduced a sound, which, he informed me, passed into the uterine cavity about six inches. He, supposing from this circumstance that she was pregnant and would abort, thought it would be best to remove the fetus at once. He then introduced "Goodell's Dilator" and, as he supposed, dilated the cervix, there being, as he remarked, "considerable hemorrhage." After the dilation he at once introduced a placental forceps, grasping what he supposed was fetal membrane, and proceeded to remove it. After repeating this several times, he found that he had been dragging down and tearing the intestines. He immediately informed the husband that the case was of too complicated a character for him to handle, and advised her immediate removal to the Paterson General Hospital. On my arrival at the Hospital the patient was in a condition of extreme collapse. Temperature was $97\frac{1}{5}°$; pulse 140, small and compressible; respiration 24; abdomen greatly distended; tympanitis over median portion; modified dulness over each inguinal region; discharge of blood from vagina; extremities cold, and patient extremely irritable and nervous. Morphin sulph. ($\frac{1}{6}$ gr.) was administered hypodermatically, and she was then rapidly prepared for abdominal section. At 9 P.M. a median incision, extending from just below the umbilicus to pubes, was made. Abdominal cavity contained a large amount of clotted and fluid blood, which was flushed out with repeated washings of normal saline solution, when a mass presented itself, consisting of omentum, intestines, uterus, and appendages, closely matted together. I then found that a rent existed in the anterior wall of the uterus, extending from near the fundus through the cervix into the vaginal vault, and that in the fundus, near the juncture of the right tube with the uterus, but somewhat above same, was a perforation, through which had been drawn the intestines, morcellated by forceps, and now held completely strangulated by the band of uterine tissue, which existed between the upper boundary of the tear and the perforation.

This perforation in the fundus of the uterus had been undoubtedly caused by the passage of the sound. The placental forceps, following the course taken by the same, passed into abdominal cavity, grasped and drew the intestines through this perforation into the uterine and vaginal cavities. The expansion of the dilator undoubtedly caused the rupture of the anterior wall of the uterus, this tear being somewhat to the right of the median line. In the right tube, at the juncture of the outer third with the inner two-thirds, was a mass about the size of a hen's egg. Whether this had been occasioned by the trauma to the parts, or was a preëxisting condition, is hard to say. Probably, however, it was the former, as an examination later proved it to be a simple hematocele, the blood partially coagulated. The intestine, with a portion of omentum, was found to be so thoroughly strangulated in the aperture in the fundus that I was compelled to divide the band of uterine tissue between the laceration in anterior wall and the perforation, to relieve the incarcerated viscera. The latter were then wrapped in a moist napkin and laid on the upper portion of the abdomen. After a careful examination of the uterus and appendages, I deemed it advisable, owing to the greatly contused and lacerated condition of the parts, to at once remove them. This was accordingly done in the usual manner. The bladder and peritoneum had been completely dissected off from the anterior wall of uterus, evidently occasioned

by the blades of dilator, which, after rupturing the uterus, had slipped out and glided along its anterior surface, thus dissecting it free from the bladder, contusing the posterior wall and fundus of that viscus. Upon removal, the uterus was found to be normal in regard to depth of cavity and character of its walls. All hemorrhage from the pelvic viscera was now entirely controlled. Left tube and ovary normal. Attention now being devoted to the intestine, I found that the injured portion comprised twenty-six inches of the jejunum and a portion of the omentum. The lower sixteen inches had been badly crushed and minced by the forceps—so much so that in parts only a shred existed of the entire lumen of the gut; a segment of mesentery was also badly torn. I then decided, notwithstanding the extremely critical condition of the patient, to resect the portion of strangulated intestine. The Murphy's button at hand proved too large for the intestine. Its use was accordingly abandoned, and end-to-end anastomosis resorted to. The mesentery having been ligated by means of the catgut chain ligature, the two ends of intestine were brought in apposition by a continuous suture, including in the stitch the peritoneal and muscular coat. This was then fortified by a row of Czerney-Lembert stitches, including only peritoneum. The stump of mesentery was also entirely covered by peritoneum. Operation being thus completed, intestine was dropped back into abdominal cavity, which was then thoroughly flushed out with normal saline solution, leaving the cavity filled with it. Abdominal wound was closed by means of silkworm-gut sutures, passing through the entire thickness of wall, including the peritoneum, and binder snugly applied. Patient returned to room, placed in bed with foot well elevated, and a large enema of normal saline solution given, which was retained. Convalescence was uninterrupted by any complication save a cystitis, which developed a few days after the operation, undoubtedly as the result of the injury by dilator to the posterior wall of bladder. This trouble was readily relieved by daily lavage of the bladder with boracic acid solution. She left the hospital, in good condition, on July 30, 1894.

At the present time—eleven months after the operation—the patient is apparently in perfect health, the cystitis having entirely subsided, as has also the vaginal discharge. There were present at operation: Doctors McCoy, Blundell, Goodrich, Harris, and Neer. The intestine exsected was measured by Doctors McCoy, Blundell, and Goodrich.

A CASE OF HEMATEMESIS.

By A. L. BENEDICT, M.D.,
OF BUFFALO, N. Y.;
LECTURER ON DIGESTIVE DISEASES, DENTAL DEPARTMENT, UNIVERSITY OF BUFFALO.

It is not customary to report cases in which the diagnosis remains obscure and in which therapeusis has failed. The following case, however, is one in which so many questions of interest center that I wish to present it, with the hope that someone's experience may give a probable answer to the questions that an autopsy alone could have settled beyond dispute:

About three months ago I was called in consultation to see Mrs. H., aged seventy, but apparently sixty, who had been ailing for some months, the symptoms being referred to the stomach, though vomiting had not been marked, and the indigestion was not greater than is often noted in dyspepsias secondary to anemia, malaria, and other conditions of vital depression. The patient was large and fat still, though relatively emaciated, the skin lying in folds about the shrunken arms and legs. There was no dropsy and nothing of significance in the condition of the heart, lungs, kidneys, etc., according to the examinations made previously by the attending physician, Dr. S. A. Dunham.

Between the left lobe of the liver and the stomach, Dr. Dunham had discovered a mass, which I, at first, took to be the ribs and cartilages, but which a more careful examination showed to be on a lower level. This projected from beneath the left costal arch, and had an area of about one inch by two and a half. There was considerable tenderness in the middle of the epigastrium, but not to any marked degree over the mass. This mass did not seem to me to be a neoplasm; it was smooth and, except that its convexity was somewhat greater than that of the normal left lobe of the liver, it did not seem to differ from the palpable part of that organ.

An appointment was made to remove the stomach contents after a test meal on the following day, but, being unable to leave the house for several days, I failed to make this examination. Hydrochloric acid was recommended, there being considerable fermentation and belching of gas. About three weeks from the time of the first examination I was asked to see the patient again. At this time the stomach and liver were more accurately mapped, though the results did not differ materially from those previously obtained. The stomach reached as low as the upper border of the umbilicus, and an area, one inch in transverse and three in vertical diameter, lay on the right side of the median line; thus, there was slight dilatation, but not enough to warrant a diagnosis of obstruction at the pylorus. Neither the right nor the left lobe of the liver could be distinguished higher than the fifth intercostal space, while the right lower border did not extend quite to the costal arch—the right lobe should be found by auscultatory percussion or by heavy ordinary percussion from the fourth rib to the costal arch. The palpable mass answered to the resonance of the liver, not to that of the stomach; that is to say, percussion over it was heard when the stethoscope was held over the liver, but only very distantly when the stethoscope was moved to the gastric area. I have reported a case of hepatic carcinoma in which the cancerous mass, though intimately connected with the liver, did not vibrate so that percussion over it could be heard through a stethoscope held over the right lobe of the liver, and, in general, I believe that a structure which is of different character from the organ with which it is anatomically connected, will act as a separate organ on examination by auscultatory percussion. For example, a lung will ordinarily conduct vibrations from any part of its superficial area, but if a lobe is consolidated, it will not vibrate in unison with the rest of the lung, and will, therefore, be marked off by auscultatory percussion as a separate organ.

The patient seemed unchanged since my first visit, except that she complained of some difficulty in swallowing. Her daughter thought that there had been some loss of flesh. I was not able to satisfy myself whether the dysphagia was mechanical, or whether it was only apparent from a growing distaste for food. An appointment was made to examine the stomach contents on the following day, but Dr. Dunham was unable to keep the appointment. It was learned later in the day that the patient had died at about the time set for the examination, there having been a hemorrhage from the stomach and a tarry stool. If the passage of the tube and withdrawal of the stomach contents had not been providentially prevented, it would have been difficult to have convinced even ourselves that our interference had not been the cause of death. I recall a similar coincidence—not in my own practice—in which a patient died shortly before the time set for an operation under chloroform. If the operation had been begun, death would certainly have been ascribed to the anesthetic.

The possibility of a relation between the examination on the day previous and the hemorrhage must be considered. Palpation was not forcible, and the percussion used in connection with a stethoscope is the very gentlest tapping with a single finger. Except that the patient was assisted a few inches nearer the edge of the bed, she was put to no inconvenience from change of posture, nor was any more tenderness elicited than is often encountered in the examination of abdomens which prove to be perfectly normal. If the hemorrhage is to be ascribed to any part of the examination, it must be to the gentle palpation of the tumor.

Regarding the exact position and nature of the tumor, there is a difference of opinion. Dr. Dunham's original, tentative diagnosis was of pyloric cancer. This was disproved by the absence of palpable tumor in the proper locality and by the absence of any such degree of dilatation as would be compatible with actual stenosis. Considering the development of dysphagia and the fatal outcome, his later diagnosis of cardiac gastric cancer has much to support it. Relying on the results of auscultatory percussion—and here there may be a fallacy, on account of lack of sufficient experience upon which to base a positive opinion—and regarding the mass as properly a *tumor*, my idea was that there had been an extension of a hepatic cancer to the cardiac end of the stomach, but that the cardia was not involved, except by the growth of the cancer. There are, however, some objections to the diagnosis of carcinoma. It is rarely the case that a cancer reaches the stage of fatal hemorrhage without previous demonstrable oozing of blood or without marked cachexia. Yet the patient, though reduced from her weight in health, was still fat, her illness had not been particularly painful, there was no obvious metastasis of the growth, there was no jaundice, the liver was small, rather than large, the complexion was not only not cachectic, but was clearer than usual, considering the patient's age. I am inclined, therefore, to set aside altogether the diagnosis of carcinoma and to consider the case as a hematemesis, due to rupture of blood-vessels in the lower part of the esophagus or the cardiac portion of the stomach, the ultimate cause of the rupture being an obstruction to the portal circulation. There were no marked signs of either cardiac, vascular, or renal disease; the spleen was not palpable. For the sake of disturbing the patient as little as possible, the back was not examined, so that there may have been, and very likely was, a moderate splenic enlargement. The liver was distinctly, though not much, contracted—a condition which, in the great majority of cases, indicates sclerosis. The tumor had not the irregular feeling of a cancer, and it did not seem to extend to the stomach, the lower border being apparently distinct. Its exact nature I do not pretend to state, but it seemed to be a somewhat enlarged left lobe.

Paul Friedrich, in an article on "Varices of the Esophagus," translated for the *Medical and Surgical Reporter* of January 25, 1895, has collected a number of cases of esophageal varix, all due to what, in a general way, may be considered hepatic cirrhosis. The slight dilatation and probable catarrh of the stomach, with the symptoms of subacidity, fermentation, anorexia, etc., may all be explained on the ground of a predisposing hepatic sclerosis. External evidences of portal obstruction are not necessarily presented, especially when the patient has been resting in bed for some time. Dysphagia, though not mentioned by Friedrich, is somewhat characteristic of varicose veins of the esophagus. There was nothing in the appearance of the patient a day before her death to warrant so grave a prognosis for the near future, and this fact alone is not only a point against the diagnosis of cancer, but is characteristic of esophageal varix. Friedrich, speaking not of the underlying hepatic condition, but of the varix, states that the only prominent symptom, and often the only symptom, is the hemorrhage. Thus, unless the first hemorrhage is recovered from, there is absolutely no warning of the critical condition of the patient, even a few hours before death. The treatment would be on the general lines of an endeavor to check hemoptysis or hematemesis. The prognosis—perhaps in the present state of ignorance, metagnosis would be a more appropriate term—is grave. The case is especially interesting with regard to the proposed passage of the stomach-tube. Its use was certainly indicated in order to throw light on the case, yet the result of such manipulation, viewed from the present standpoint, would have been truly awful. Everyone, from the man whose prudence amounts to cowardice to the one who regards radical and scientific investigation as of paramount importance in any case, can draw the moral to suit his own views. The writer feels sure that he has prolonged life by the use of the tube, when subsequent events have shown that danger must always have been imminent from its use. Comparing such cases and the one here cited, the indication is for a mingling of caution and boldness. It is to be regretted that an autopsy could not have been secured in the present instance; but, whether the case was really one of esophageal varix or not, there is sufficient resemblance to that almost unrecognized disease to warrant using the facts and speculations which are contained in this article to call attention to a problem of diagnosis which we ought to learn to solve before death.

SPECIAL ARTICLE.

THE STERILIZATION OF HYPODERMIC AND OTHER SYRINGES BY BOILING.

BY CHARLES A. POWERS, M.D.,
OF DENVER, COL.

HOWEVER simple and efficient may be our present aseptic technic, there yet remain many minor details in which our methods fail to give entire satisfaction. We have hitherto been unable to sterilize injection syringes in which the piston and washers are made of leather. This difficulty is now, however, happily overcome by Hofmeister of Tübingen, who, in the *Centralblatt f. Chirurgie*, July 4, 1896, sets forth a method by which we may render these important instruments, absolutely aseptic.

His procedure rests on the principle that leather may be boiled at will in plain water after previous hardening in a formalin solution. The plan is as follows:

1. Only such syringes may be sterilized as consist of glass, metal, and leather. The metal parts must be united by solder or screws, rather than by cement.

2. The piston and washers are removed and freed from lubricating fat by ether.

3. They are then placed in a two to four per cent. formalin solution for twenty-four to forty-eight hours.[1]

4. After the formalin has been washed off, the syringe may be put together and is then ready for boiling.

5. All air should be removed by working the piston back and forth while under water; the syringe may then be boiled at will in plain water (thirty minutes should suffice).

I have thoroughly tested this procedure on a number of hypodermic, exploratory, and aspiration syringes, and can verify Hofmeister's statements in every particular.

Apparently the only change which the leather undergoes is a darkening and a slight thickening. Previous to immersion in the formalin solution, it may be well rubbed with gauze, dipped in ether, and after sterilization, it is to be again lubricated with sterilized oil. If the piston consists of two pieces of leather separated by an oil-space, I have found it well to insert the first of these in the glass barrel before boiling. A moderate swelling of the leather may necessitate trimming its edge with a sharp knife.

I have put an ordinary hypodermic syringe through this sterilization process four times, at intervals of two days, without apparent change in the leather. What its limitations are as regards repetition, time will determine. It may be that the leather will have to be removed from time to time. However, this may be, there are so many sources of infection in these syringes (exploratory aspiration of pus, for instance), and absolute asepsis when making injections is so much to be desired, that I am certain that this simple procedure will find wide employment.

[1] I have used a four per cent. formalin solution for twenty-four hours.

MEDICAL PROGRESS.

Pneumothorax Cured by Operation.—UNVERRICHT relates in the *Deut. med. Woch.*, for May 28, 1896, a case of "pneumothorax acutissimus" occurring in a young man aged twenty-three. The patient had been under treatment for some months for pulmonary tuberculosis. A sudden attack of pain in the left side and great dyspnea indicated pneumothorax, which the physical signs vaguely confirmed. The great mobility of the inserted hollow needle and the escape of air through it, when submerged, made the diagnosis sure, and a permanent fistula was established in the sixth intercostal space. The dyspnea was at once relieved. There was a considerable discharge from the wound of a purely serous character. This rapidly diminished, and in twelve days the fistula had closed, and all physical signs of pneumothorax had disappeared. The tubercular process spread, however, and by a strange fate, the patient died two months later with pneumothorax of the opposite side. The autopsy showed extensive tuberculosis of both lungs with cavities. There was marked right pneumothorax, but on the left there was no indication of the preëxisting pneumothorax, or the operation for it, excepting some slight adhesions.

This treatment is advocated in cases in which it is reasonable to suppose that the lung is distensible; and in all cases of pneumothorax acutissimus when immediate death from dyspnea is threatened.

Pain in Chronic Aortitis.—DURR (*France Méd. et Paris Méd.*, 1895, No. 32) points out that the existence of deep-seated retrosternal pain is often the diagnostic symptom of chronic aortitis. If the pain shoots in any direction, the presumption is that the disease has spread beyond the aorta, *e.g.*, into the coronary arteries, with symptoms referable to the heart muscle, or into the branches of the aortic arch with pain in the head or arms.

An anxious feeling, unaccompanied by respiratory disturbances, is characteristic of chronic aortitis; but the two absolutely pathognomonic symptoms are (1) an extension of the cardiac dulness in the second intercostal space to the right of the sternum, indicating an increase in the transverse diameter of the aorta; and (2) a filling up of the right intraclavicular fossa—the result of an increased length of the aorta. Of secondary importance is any change in the character of the second heart sound, for this depends on alteration of the valves, which is not a necessary concomitant to aortitis.

A Still More Extensive Breast Amputation.—TANSINI (*Rig. Med.*, April 5, 1896) holds that in the attempt thoroughly to remove all lymphatic glands, which may possibly have become involved, secondary to cancer of the breast, recurrence in the skin has been overlooked. He calls attention to the frequency of recurrence of this sort in the form of isolated nodules in or near the scar. In order to avoid such recurrence, he removes the overlying skin of the whole breast, and a strip about four inches wide from the breast into the axilla. To cover the defect, a flap is dissected from the back, with its pedicle near the axilla, and stitched in position over the wound.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,

SATURDAY, AUGUST 22, 1896.

THE END OF QUACKERY IN BELLEVUE HOSPITAL.

DURING the past two months there has been carried on in Bellevue Hospital by the Commissioners of Charities, bound by oath to administer the charity hospitals of the municipality to the greatest benefit of the suffering sick, such a piece of quackery against its patients, and thereby there has been offered such an insult to the medical profession and the intelligent members of the community as we hope we shall never again have occasion to witness.

We now chronicle with becoming satisfaction the demise of the "drink cure" experiment. We hope soon to be able to furnish our readers a full account of the obsequies which the Commissioners are giving the corpse. The NEWS takes to itself no little satisfaction for the part it has taken in pricking this little bubble of the Commissioners. It brought to light the true inwardness of the undertaking by its discovery and exposure of the fact that the "cure" was backed by an incorporated, capitalized company. The consternation of the Commissioners occasioned by this exposé was such that the NEWS believed they would see the error of their way and immediately discontinue the experiment. But they have seen fit to persist in their arbitrary course, and in spite of the repeated admonitions of those who could foresee the result, they have continued in their insane efforts until they have made themselves not only ridiculous, but infamous. Now they have no credit and no thanks from anyone for the cessation of the experiment. "The cure has succumbed from natural causes," so say the Commissioners, and they are desirous of burying it without an autopsy. Monsters and abnormalities of all kinds interest, however, and we purpose looking into the immediate cause of dissolution in this case.

For the past month the spurious visiting physician to Bellevue Hospital has been very direlict in his duties; in fact, for two successive weeks of that time he did not favor the institution with his presence. During this period, the spacious hospital wards, which had been placed at his disposal, were useless, and the suffering sick were excluded, and that, too, at a time when the heat was the most trying and the demand for succor the greatest. To the shame of the Commissioners, be it said, that during a crisis that called for instantaneous and unequivocal action, they remained as impassive as though they themselves had been seized upon by the *rigor mortis* that had already laid hold of their darling foster child—the subsidized drink cure. Even the Warden of that institution, he who spoke from the depths of personal medical wisdom two days after the "cure" was instituted and proclaimed it "a Godsend," when informing the President of the honorable board of Commissioners of Dr. Oppenheimer's direliction frankly confessed his inability "to comprehend the situation in its present advanced form."

Even though the Commissioners hesitated at this juncture to revoke the privilege granted the owner of a secret remedy, they might still have sought and found escape from their predicament by enforcing a law of their own making, that all visiting physicians shall visit the Hospital at least three times a week. The ostensible reason for this delay was the desire to give the individual

Commissioner, who had stood sponsor for the experiment, an opportunity to prepare a report substantiating, as far as possible, his advocacy of an experiment which he and his fellow Commissioners knew in their inner consciousness was utterly futile; for failures, and numbers of them, are within their personal knowledge. The real reason, however, which they endeavor to conceal, was the hope that the MEDICAL NEWS, and others of their critics, would tire of their onslaught upon them, and when the subject had ceased to figure in the eye of the public, they could slip out of their unfortunate position without observation or comment.

Now, however, we call upon the Commissioners of Charities to put upon record their opinion of the pitiable and ignominious failure of their first effort in experimental medicine, and insist that it shall be couched in such language that, at least, he who reads between the lines, may detect their sincere sorrow and regret for their conduct. If they do not do this, we shall feel, so long as they remain in office, that being dominated as they now appear to be by their impulses and emotions, we shall not be secure from future trials of whatever silly fad they, their families, or their advisers may happen to embrace, whether it be Christian science or the Kneipp cure.

The real shortcoming in the present Board of Charities Commissioners is that they are boys in reality, although the Mayor would have us believe that they are "boys" only by his facetiousness.

ELECTRIC CURRENTS AND COMFORT.

EVER since the earliest discovery of electricity as a force, it has been a favorite popular theory that it was closely related in some way to "vital force," if, indeed, it was not a form of it. And to this day the general impression among the laity is that simply to charge the body or any part of it with electricity is to "fill it with new life," and that any belt, battery, or even hair-brush, which will give off electricity to the body is supplying it with force which can be directly used in its processes. Stories are told with bated breath of dead men brought to life by electricity and enabled to walk, talk, eat, etc., as long as the current was kept up; much as in the rural districts the belief obtains that dying men can be kept alive for hours, or even days, "onnaterally" by pouring frequent doses of whisky down their throats. Indeed, we are sometimes gravely asked whether the "vital spark" is not really electric!

That this implicit childlike confidence in the virtues of any form of the current is responsible for many of its most brilliant therapeutic triumphs, can scarcely be doubted; indeed, it is a question whether at least half its reputation as a remedial agent is not due to the vivid expectancy which it excites in the minds of our patients.

Great and genuine as are the therapeutic effects of the current, yet outside of electrolysis and certain nerve and muscle results, we are quite in the dark as to how they are produced, and any developments, however slight, which point in this direction are of interest. Dr. Augustus Waller has been conducting experiments of late upon infusoria and other floating organisms with this problem in view, and obtains some curious results. If a current be passed through a solution containing paramesia, the whole group of organisms is at first greatly disturbed, but shortly they begin to swim steadily toward the cathode in converging lines. If the current is now reversed, they promptly "right about face," and begin swimming toward the new cathode. Evidently they are more comfortable swimming with the current than against it. Other microörganisms tend to swim against the current, and others at right angles to it, but all are definitely and markedly affected by it. The same was found to be true of larger and more complex organisms—for instance, tadpoles, a group of which is at first thrown into wild commotion by the current; and when this subsides, is found to be arranged with the heads of all its members pointing toward the positive pole, letting the current pass through them from head to tail. A very weak current will produce no apparent effect upon tadpoles lying "head on" to it, but will cause those lying at right angles to wag their tails about. Is it possible that the soothing and pain-relieving effects of the constant current, and especially of a discharge from a "static" machine, may be due

to a similar effect upon the fixed cells of our bodies, and that the popular belief that beds should be arranged so that we can sleep with our heads pointing north, and allow the polar currents to pass through our bodies lengthwise, may have some shadow of scientific foundation?

ECHOES AND NEWS.

Meeting of the Tri-State Society.—The eighth annual meeting of the Tri-State Medical Society of Alabama, Georgia, and Tennessee, will be held in Chattanooga, Tuesday, Wednesday, and Thursday, October 13, 14, and 15, 1896.

Annual Meeting of the Academy of Railway Surgeons.—The third annnal meeting of the American Academy of Railway Surgeons will be held at Chicago, in the Auditorium, on Wednesday, Thursday, and Friday, September 23, 24, and 25, 1896.

Suffering in London.—A serious shortage in the water supply of this great city is reported both by the lay and medical press. From these it is hard to determine whether the increase of mortality in the eastern districts of the city is due to this cause or not, but it is generally admitted that the amount furnished falls much below what is required for the comfort of the population, particularly the improvident and poorer classes.

A New Home for the New York Skin and Cancer Hospital.—The northwest corner of Nineteenth street and Second avenue is being cleared to make ready for the building to be erected for the Skin and Cancer Hospital. For fifteen years this growing institution has occupied No. 234 East Thirty-fourth street, which has now become altogether inadequate. The new hospital is to contain all modern improvements, including a most complete system of baths, and will be erected within a year, at the cost of $80.000.

Changes in King's College.—Professor Lionel S. Beale has severed his connection with King's College, London, in which he occupied the chair of medicine. He also resigns the office of physician to King's College Hospital. Professor F. Jeffrey Bell, after seventeen years of distinguished service as professor of comparative anatomy in the same institution, has also resigned. The Council of the College have appointed Dr. Burney Yeo to succeed Dr. Beale, and Professor Curnow to occupy the chair of clinical medicine made vacant by the death of the late Sir George Johnson.

Organization of Opticians.—The opticians of Pennsylvania are endeavoring to form a State organization with the following objects: First, to elevate and advance the profession and the mutual intercourse and benefit of its members; second, to encourage opticians to perfect themselves in the study of optics and the scientific adaptation of lenses in correcting errors of refraction; and, third, to discourage the haphazard and indiscriminate sale of spectacles by irresponsible and ignorant persons. Is it not probable that the opticians of Pennsylvania, in this endeavor to broaden the scope of their work, may be tempted to undertake duties for which only the trained oculist is prepared?

Defects of Vision Among English School-children.—In a report of the examination of more than 8000 children in the elementary schools of London, Mr. Brudnell Carter stated that thirty-nine per cent. were found to have normal vision in both eyes, and the same percentage had subnormal vision in both eyes. The remainder were defective in one eye, while its fellow was perfect. As to sex, there were ten per cent. more boys than girls with normal vision. Myopia was of infrequent occurrence, and, contrary to the experience of similar observers in the German schools, no increase in the per cent. of defects was discovered among children of the older than among those of the younger grades.

A Just Protest.—An appeal signed by more than one hundred physicians in the United States will be sent to the General Council of the International Red Cross Society, calling attention to the non-observance by Spain in the Cuban war of the stipulations unanimously agreed to at the congress held by the Society, in which Spain, as a nation, took part. It was at the conference specified that in all international or civil wars the hospitals, wounded men, surgeons, and nurses of the enemy, should be respected by the contending parties. Attention is called in the physicians' protest to the frequent mention made in Spanish official reports of the capture and destruction, by the Spanish troops, of the hospitals of the Cuban insurgents.

Painless Death for Incurables.—A popular discussion has been inaugurated by the sermon of a leading California minister, in which he advocated as a practice, the relief of the incurably ill or mortally wounded by speedy death. His suggestion has been met by strong opposition based upon the sixth commandment as a text. As the physician will find himself called upon to act in the capacity of judge as well as executioner in any such emergency, it is best to leave to his ethical sense and the dictates of his own conscience to determine just where his duty lies in each individual case. It is needless to say that no one would lightly assume such grave responsibilities.

Medicine as a Moral Agent.—Whereas formerly the sulky, stupid, or ill-tempered boy was commonly relieved of such distemper by the master's rod, it is now believed by a certain school of psychologists that with the judicious use of internal remedies his case is better reached than by this time-honored method of counter-irritation. A clearer insight would discover the salutary effects of a dose of castor oil in many instances. The writer once knew the wife of a physician who habitually administered purgative doses of calomel to her two little boys with the sole intention of improving their dispositions. No less an authority than Dr. Lauder Brunton has directed the attention of the profession to the fact that many quick-tempered persons are really victims of masked forms of gout or rheumatism,

and may be relieved by appropriate remedies which he has facetiously called *temper-powders*.

A Hygienic Sewing-Machine Treadle.—An improvement to the sewing-machine is announced, which will be joyfully welcomed by all of us who have working-women as patients. The old treadle, with its up-and-down movement of the entire limb, and wearying, cramping strain directly upon the muscles of the calf and front of the thigh, and indirectly upon the lumbar region, is to be abolished, and its place taken by a hanging platform, swinging pendulum-fashion. Upon this the foot rests easily and is swung backward and forward, the momentum being furnished mainly by the weight of the foot alone, instead of by that of the entire limb as before. The thigh remains almost motionless, and the economy both of effort and discomfort is most decided. Either foot can be used alternately or both together, thus giving relief from the monotony of the constant movement.

Nordau's Methods of Work.—Dr. Max Nordau's name was originally Dudfield, and Nordau was at first simply a pseudonym, which, with the consent of his father, he afterward legally assumed. He lives in Paris above a wine-shop, and here is his description of his modes of work: "I spend my days in paying visits to my clients and receiving visitors. In the intervals I attend to my journalistic duties, for I am the Paris correspondent of the *Vossische Zeitung*, of Berlin, and I also contribute to the *Frankfurter Zeitung*, writing on all subjects. It is not till after dinner, that is to say, at about half-past eight, that I sit down to my table to write my books. I then work till eleven o'clock, or midnight, as the inspiration goes. When I set pen to paper I am sure of the last word of what I am going to write as I am of the first. But I find it hard to sufficiently concentrate my mind at first, and the work of the first hour is about equal to the work of a quarter of an hour later."—*Literary Digest*.

Obituary.—In the death of Dr. Joseph Meredith Toner of Washington, D. C., on August 1st, the profession of America has lost one of its most distinguished members. For almost a half century he has made the influence of his energetic and magnanimous nature felt throughout its ranks. In 1871 he founded the Toner Lectures by placing $3000 in the hands of trustees. By the proceeds of this at least two lectures, based upon original research, are annually secured. His library, containing many rare and valuable volumes, has been placed in the Congressional Library at Washington, where it is kept separate from the other books. Dr. Toner was born in 1825, graduated in medicine from Jefferson Medical College in 1853, and after two years settled in Washington City, where he has since been actively engaged. Dr. Toner served as president, and subsequently as trustee, of the American Medical Association; he was vice-president of the International Medical Congress in Philadelphia in 1876, and has occupied the highest positions of honor in many smaller associations. His contributions to medical literature show him to have possessed a mind naturally broad and philanthropic, which he had widely cultivated.

New Method of "Doctoring" Milk.—It has been discovered that milkmen in Bordeaux, France, were in the habit of using certain yellow powders to preserve their milk. M. Denigès succeeded in obtaining possession of three samples of this powder and subjected them to chemical analysis. "This analysis showed that two of the powders were composed wholly of neutral chromate of potash, that the third was a mixture of one part of bichromate of potash and two parts of neutral chromate, and that the suspected milk had been adulterated with the latter in the proportion of 0.30 gm. to the liter (5 grains to the quart). The alkaline chromates are powerful antiseptics, capable, even in small quantities, of retarding lactic fermentation if not of stopping it completely. But because of the pernicious action of these salts on the organism they ought to be completely excluded from food substances, and particularly from milk, of which many young children drink relatively large quantities. These chromate powders are sold in packages of 2 gm. (30 grains) each of which should suffice to preserve about fifty quarts of milk, which would correspond to 0.04 gm. (0.6 grain) of antiseptic to the quart, evidently a minimum proportion. But it is likely that the milkmen will be induced to augment this quantity, either because it is insufficient to preserve the milk during the high temperatures of summer, or in order to restore the color of the liquid, due normally to hemolutein, a yellow pigment, when it has been lessened by skimming the cream, adding water, or by inferiority of quality, and thus to cause a mediocre product to pass for a milk of greater value." Knowledge travels rapidly, and even American milkmen may not be above such practices. Let us hope that the inspector may be as canny.

CORRESPONDENCE.

"THE STRYCHNIA CURE OF ALCOHOLISM AND THE OPIUM HABIT."

To the Editor of The Medical News:

Dear Sir: Will you allow me a short space in which to disagree with Dr. C. L. Dana in his advocacy of "Strychnia Cure of Alcoholism and the Opium Habit." I could not but disagree had I read nothing but the title, because it implies the cure of a habit with a drug.

A habit is an ingrained quality of the organism, a result of more or less prolonged impress of the different factors of the environment of that organism. It might be said to be a natural state, however artificially produced.

Alcoholism is a state of the nervous system produced by the use of alcohol through a long period of time, and most often through more than one generation. It is a nervous system so accustomed to the stimulating and sedative effects of alcohol that it can have no stability without its accustomed food. Indulgence in this habit is at the expense of all the individual's moral interests; all of his family, business, social, and religious interests suffer. If the individual can be made to understand this, and if he has any family, business, social, or religious ties, pulling him in the other direction, he may be cured. To-

effect a cure he must understand that the responsibility is all his own.

While, of course, it is commendable in our profession, as in all others, to live up, as close as may be, to the never-say-die principle, and strive always to find a cure for everything, I think we may in this effort occasionally do harm. We certainly do harm when we lead inebriates to believe that they can be cured by drugs. What their appetites and longings require is a stimulant and a sedative, and to give them temporary relief with strychnia and bromids only leads them to believe that they can be cured without any exertion of their own. Only a few days ago I heard a young man say that he was not afraid to drink now, because he could take the Keeley Cure once a year and get straightened out again. Such perfect faith as this is not at all uncommon, and the flattery of imitation of the object of that faith by leading physicians and hospitals does not tend to weaken it.

My experience has been, and, I think, it will find substantial support in the experience of others, that an inebriate who still has some regard for family, social, business, or religious ties can be benefited if he can be made to understand the extent of the danger. Or, in other words, if he has anything left upon which to build appetite and desires stronger than that for the drug.

All inebriates are such through ignorance alone, and many among the better classes can be cured by making them see that all their better interests are in the gravest danger. This may be done by showing them that, even though they may not be *ruined* by it, at best it has a very bad effect on the stomach, liver, and nervous system, and that the appetite they build up is likely to be transmitted to their offspring. Those who are stupid and uneducated, or have no moral ties, such as we see most often in hospital practice, offer little encouragement in the hope of curing them. To give them a staff to lean on, it seems to me, is not the way to give them confidence in themselves, it gives them confidence in the *staff*, and therein lies the harm. Many of these having no family, social, business, or religious ties have nothing but their drink appetite to make life worth living. The attempt to cure these with a drug is just as rational as the attempt to cure the better class with a drug, and is to be commended more for courage than judgment.

Yours,

GEORGE S. BROWN, M.D.

BIRMINGHAM, ALA.,
August 11, 1896.

HYPODERMOCLYSIS IN THE TREATMENT OF THERMIC FEVER.

To the Editor of THE MEDICAL NEWS:

DEAR SIR: The season of the year and the recent universal experience of prolonged high atmospheric temperature, with the likelihood of more of the same to follow, will sufficiently explain my apparently premature communication.

On page 1132 of the American Text-book of Applied Therapeutics, I suggested, upon theoretical grounds, the possible value of hypodermoclysis as an adjuvant in the treatment of some serious cases of thermic fever.

Recently, while temporarily in charge of the medical wards of the Pennsylvania Hospital for Dr. J. C. Wilson, I have had the opportunity to observe the effect of the measure in one case where its beneficial action was sufficiently marked to somewhat confirm my theory.

My reasons for thinking of the possible value of hypodermoclysis in these cases are, briefly, as follows: Thermic fever usually prevails after a high external temperature has persisted for at least three or four days. During these days the body has been losing much fluid through perspiration. Certain cases of thermic fever are, for a variable length of time after the reduction of temperature, in almost as grave a condition as before such lowering of body-heat was accomplished. Inasmuch as in a very large number of cases of thermic fever the symptoms rapidly disappear after reduction of temperature, there must be some factor other than the high bodily temperature alone, which continues to be present in those cases wherein improvement fails to follow the fall in the bodily temperature. If, in such obstinate cases, bleeding is performed, it is found that the blood flows very sluggishly from the vein, that it is thick and tarry, and that it is evidently lacking in its fluid portion. Such being the case, it seems not unreasonable to surmise that the persistence of coma, stertor, muscular rigidity, etc., may be due to the lack of water in the blood. Why some cases should suffer from this condition, while others escape, it is difficult to say, but careful inquiry might elicit some facts in regard to the amount of perspiration lost, the amount of fluid ingested just prior to the attack, and other features of the various cases that might throw some light upon this difference in course. Being quite imbued with the plausibility of this theory, I requested the Resident Physician to employ hypodermoclysis in this class of cases of thermic fever. Such a case occurred a few days ago in the person of a contractor, aged forty-eight years, who was brought to the Hospital from the Broad street station at 8.30 P.M., on August 12th. He was rubbed with ice on the way to the Hospital, in the ambulance, but on admission he was found to have a temperature of $109^{3}/_{5}°$; pulse 154; respirations 33. He was unconscious, but not convulsed, with moderately contracted pupils and markedly stertorous respiration. He was at once put in a tub of iced water and given nitro-glycerin ($\frac{1}{100}$ gr.) hypodermically. After being in the tub for five minutes he was removed, placed on a bed, and was vigorously "ironed" with ice. At seven minutes after nine his temperature was $103^{2}/_{5}°$; pulse 146; respirations 32 and irregular. At this time he began to have spasmodic contraction of the extremities. At 9.35 he became very cyanotic, the respirations became slow and labored, requiring, finally, the use of artificial respiration and the battery. At 10.05 his temperature had remained below 103° for some time, but there was marked twitching of the right side of the face added to the previous spasmodic contractions. The pulse at the wrist was imperceptible at this time. At 10.18 he was "fearfully cyanotic," and the jaws became rigidly fixed. He was bled from the median basilic vein to the

extent of sixteen ounces, immediately after which the respirations became more deep and quiet and the spasmodic twitching lessened. At 10.25 half a pint of sterilized normal salt solution was slowly introduced beneath the skin of the pectoral region on both sides. The pulse at once improved, and at 10.40 he became conscious and gave his name, while at about the same time the twitchings ceased.

Nothing further of interest has occurred up to the present time, the patient being thoroughly rational, perfectly comfortable, and showing no symptoms, save for slight elevation of temperature, that is easily accounted for by a quite severe glossitis that has resulted from a lacerated wound of his tongue, produced by his teeth during his period of pseudo-convulsions.

The case will probably be reported by the Resident Physician, Dr. J. C. Starbuck, in a future paper upon the cases treated by him during the summer. I have made this preliminary report in order to draw attention at once to an adjunct in the treatment of thermic fever, the action of which much impressed those who saw it used in the case here related, and in the hope that the use of hypodermoclysis may prove to be of value in this extremely obstinate condition sometimes present in thermic fever.

Should any of your readers employ the measure, I should be very glad to learn whether its further use bore out the theory above advanced, and confirmed the advisability of still further adopting this as a procedure of some value.

Sincerely yours,

FREDERICK A. PACKARD.

PHILADELPHIA, PA.,
August 14, 1896.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.

Sixty-fourth Annual Meeting, held in Carlisle, England, July 28, 29, 30, 31, 1896.

(Continued.)

THE SECTION ON MEDICINE.

FIRST DAY—WEDNESDAY, JULY 29TH.

On taking the chair, GEORGE F. DUFFEY, M.D., of Dublin, delivered a brief address in which he expressed his gratitude for the compliment paid, not so much to himself personally as to the "Irish School of Medicine" in selecting him as chairman of this Section. He indulged in a number of happy references to the early history of the Association, mentioning the name of William Stokes as indissolubly connected therewith. The Section, he said, was to be congratulated upon the interesting subjects which had been selected for its discussion at this meeting. From the beginning the attendance was large and intense interest was manifested.

The first subject presented was:

THE TREATMENT OF CARDIAC FAILURE.

This discussion was opened by an exhaustive speech from Sir Thomas Grainger Stewart, who first laid emphasis upon the great value of rest, and then referred to "hope" as an important factor in the treatment. He next touched upon the usefulness of a well-ordered dietary in the management of cardiac disease. The treatment by systematic exercise and baths after the methods of Dr. Schott, at Mannheim, occupied the attention of the speaker for quite a time. In this connection two very excellent skiagraphs of the heart were exhibited, showing the position of the organ from in front and behind with singular clearness of detail. He then spoke of drugs and also considered paracentesis as more or less helpful in the management of severe cases. The chief thoughts of those who joined in the discussion centered about the question of the value of the Schott method, and while many, perhaps the majority, were emphatic in their expressions as to its undoubted value, others were deeply impressed with the disappointment they had found in its results. Dr. Herringham, in his remarks questioned the value of auscultatory methods in determining heart disease, which drew a reply from Dr. Bezly Thorne. Dr. Leith thought the carbonic acid in the baths at Nauheim an important element of the treatment, while Drs. Liddell and Edgecombe claimed that the sulphur baths at Harrogate were quite as effectual as the Nauheim waters. Dr. Byrom Bramwell advised rectal feeding.

SECOND DAY—THURSDAY, JULY 30TH.

The Section opened promptly at 10 o'clock and without delay the chair called upon DR. FREDERICK TAYLOR to open the discussion upon

ANEMIA.

The author considered three distinct varieties of this malady—namely, splenic anemia, chlorosis, and pernicious anemia. He said a classification including the secondary varieties would involve too much detail, and would not be considered in the present discussion. Attention was directed to the occurrence of sclerosis in the spinal cord in cases of profound anemia which had been observed by Dr. James Taylor. Rest was recommended as the most important item in the treatment of chlorosis, while arsenic gave most favorable results in the pernicious form. Splenic anemia was really more common than was generally believed, and not infrequently mistaken for lucocythemia. An active discussion followed which was interrupted to witness a lantern demonstration by Dr. James Taylor, of the sclerotic changes in the posterior and lateral columns of cord that occurred in certain cases of profound anemia, and others by Dr. Ransom, showing in a series of slides the changes observed in the kidneys, liver, spleen, and intestines, and also the fact that in his experience the iron deposits in the liver were in the cells. The further discussion of this subject continued until almost two o'clock, and the want of time made it possible to hear only two other papers, which were presented without discussion.

THIRD DAY—FRIDAY, JULY 31ST.

TUBERCLE.

In the light of the deliberations of the Royal Commission on Tuberculosis, this subject had a peculiar interest, and was wisely selected as the chief topic for Friday's consideration. Dr. Moore opened with an exhaustive

paper, in which he seemed deeply impressed with the need for some measure whereby the great mortality from this disease might be reduced. He first dealt with the bacillary origin of tuberculosis, and then briefly considered the early signs of consumption. Next he considered the damage which tuberculosis does and the various modes of infection. Methods of prevention, hospital treatment, and the therapeutics of the disease received due attention. Finally the subject of compulsory notification was treated. On this point, Dr. Moore thought that, while compulsory notification of all cases was not feasible, yet voluntary notification should be encouraged, and that notification of death from tuberculosis should be compulsory. Dr. De Havilland Hall pointed out the importance of the removal of adenoids and hypertrophied tonsils; these, with the nasal mucous membrane, were the frequent sites of entrance of the bacilli. The good results of guaiacol were mentioned by Dr. Shingleton Smith. At the suggestion of the Chairman, a resolution was offered requesting the council of the Association to use its influence in impressing the Government with the necessity: (1) That provision should be made, at the public expense, for bacteriological laboratories by all sanitary authorities, where the sputum of patients suspected to be suffering from tuberculous disease may be examined and reported upon; and (2) that on the discovery of pulmonary phthisis in any individual of the poorer classes, public provision should be made for the treatment of such case in a public institution, provided for the purpose at public expense and by voluntary contributions. In speaking to this resolution, Professor Gairdner said: "The sooner that tuberculosis is looked upon as a plague, and treated as such, the sooner will the terrible mortality from it commence to diminish."

Section on Surgery.

First Day—Wednesday, July 29th.

The work of this Section opened with a discussion on

the surgical treatment of prostatic hypertrophy,

by David McEwan, M.D., of University College, Dundee. He discussed the various theories offered in explanation of the effect of castration in this disease. He accepted the statement that the very large, soft prostate is more readily influenced by removal of the testes than the hard, fibroid form. From a study of the records of thirty-seven cases of resection of the vas, he found that as many as twenty-six cases were successful. He had, himself, performed double orchectomy in three cases, with good results, and had obtained some slight benefit from resection of the *vasa deferentia* in one case. Mr. Reginald Harrison, who has had a larger experience than any other English surgeon in vasectomy, reported that out of ten cases of bilateral division of the vas deferens, five had received great and lasting benefit. In twelve cases, one vas only was divided, but even then benefit was secured. Mr. Mansell Moullin thought that in advanced age double castration was the operation to be advised, but that earlier in life prostatectomy was to be preferred, if the condition of the patient allowed of such an operation. Dr. Sandberg of Bergen, expressed astonishment that Professor Senn of Chicago should have expressed the fear that castration would be resorted to for vesical calculus, chronic cystitis, and malignant disease of the bladder, if it was recommended for prostatic hypertrophy, and warmly maintained that surgeons in Norway could not be guilty of such surgery, whatever American practitioners might do. Professor Cameron of Toronto, Canada, related his experience in bilateral castration, and reported nineteen cases: One patient died of suppression of urine on the fourth day, and in two others mental symptoms developed. In one of these an extract of fresh sheep's testicle was administered, *à la* Brown-Sequard, and improvement quickly followed.

Dr. Lauenstein of Hamburg, read a paper upon

subphrenic abscess

And reported six cases. He insisted that all these cases should be handed over by the physician to the surgeon for operative procedure. This suggestion proved rather startling to an audience of English surgeons.

Dr. Snow read a paper on

my experience in operations for malignant disease of the breast,

in which he made special reference to the insidious marrow lesions to which he has frequently called attention.

Mr. Stoker gave a demonstration of the

treatment of ulcers by oxygen gas.

Lantern slides were shown and two patients exhibited, in which marked success had attended the use of the gas.

Second Day—Thursday, July 30th.

The greater part of this session was occupied by an interesting discussion upon the

surgical treatment of appendicitis.

The subject was introduced by an admirable paper from Dr. MacDougall. In this, particular stress was laid upon the rapidly fatal termination of many cases when not operated on, and he advised early operation in cases presenting urgent symptoms, but did not consider operation should be the rule in every severe case. He favored removal of the appendix only in those cases where it could be easily accomplished without breaking down protective adhesions in so doing. In this advice all the subsequent speakers concurred. Mr. Southam spoke of relapsing appendicitis, of which variety he reported ten cases. He expressed the belief that such cases should be subjected to operation after the second attack. Mr. Morton of Bristol pleaded for operative treatment in all severe cases, as he thought it impossible to be sure that general peritonitis had not just begun or that a collection of pus was not already present, which might rupture at any moment and set up general inflammation. Mr. Jordan Lloyd of Birmingham advised a vaginal or rectal evacuation when the pus was within the pelvic cavity. Others spoke of the necessity for rapid operation, and also considered early operation imperative in certain varieties of cases, which they endeavored to define. Mr. Banks doubted if mischief in the cecum might not be the cause of many abscesses supposed to arise from the appendix.

Dr. Blocii of Copenhagen called attention to the

possibility of removing certain tumors from the kidney, instead of performing nephrectomy.

DR. CAMPBELL of Belfast spoke of the advantages of the sacral methods of operating in diseases of the rectum and adjacent organs. Dr. Banks related his experience with the Murphy button, which had been favorable, as a rule. Mr. Tubby presented a paper upon

METATARSAL NEURALGIA.

Abscess of the liver was next considered.

THIRD DAY—FRIDAY, JULY 31ST.

THE SURGERY OF THE SUBPERITONEAL TISSUE

was discussed in a valuable paper by Mr. ANDERSON, in which he accurately described the position of this tissue and the various morbid conditions to which it was subject. This paper gave an exhaustive treatment of this broad subject, the material for which was chiefly drawn from current medical literature. Dr. MacDougall spoke of its bearing upon certain cases of appendicitis. Cases of sarcoma and lipoma located in this tissue were reported by members. Dr. Sandberg of Bergen advocated the use of tuberculin as a therapeutic agent. A number of interesting cases illustrative of diseases and injuries of the spinal column were reported, and a discussion upon the merits of operative treatment in such conditions naturally ensued. After this DR. BRONNER read a paper upon

OPERATIONS ON THE MASTOID,

and the work of the section was concluded by a presentation by Mr. Albert Morrison of the report of two cases of Jacksonian epilepsy.

SECTION ON OBSTETRICS AND GYNECOLOGY.

The chairman delivered an address upon

THE MORE RECENT DEVELOPMENTS OF GYNECOLOGICAL SURGERY.

He said that in no department of medicine have advances been more repaid, in none has the evolution of our art been more conspicuous and in none the results more brilliant than in gynecology. The great problem now is uterine cancer. When we consider the increasing prevalence of cancer of the uterus it is not to be wondered at that its surgical treatment during the last decade has come into special prominence. There cannot be fewer than eight thousand women now suffering from this disease in England and Wales. Of all women who die of cancer one-third die of cancer of the uterus. The treatment is removal at as early a date as possible. Not only the immediate but the remote results of vaginal hysterectomy are eminently satisfactory. For vaginal hysterectomy to be successful, mobility of the uterus and freedom of the fornices are the essential points. All partial and incomplete operations are practically valueless. If the whole of the diseased structure is not removed the patient, in the majority of instances is worse than before.

During the past ten years, both in private and hospital practice, he had seen over three hundred cases of malignant disease of the uterus. He has been greatly surprised to see how few among these conformed to the requirements likely to make the operation of permanent value to the patient. The responsibility for this rests both with the patient and the family physician.

Hysterectomy for conditions other than cancer requires very careful guarding. Like the removal of the uterine appendages for inflammatory disease, this operation bids fair to be overdone. Vaginal hysterectomy, as recommended and practiced successfully by some American surgeons for puerperal sepsis and puerperal thrombosis, can very seldom be reasonably advised for three reasons (1) The onset is so sudden and the general systemic infection so rapid that no purely local measures are of any avail. (2) In cases of slow infection from foci in the interior of the uterus, satisfactory results can be obtained by irrigation and curettage. (3) The condition of the septic puerperal woman is unfavorable for such a serious surgical procedure. The *post-partum* condition, which lends itself most readily to vaginal hysterectomy, is that first mentioned by Sänger and discussed recently by Spencer and Eden—viz., deciduoma malignum.

Abdominal hysterectomy for bleeding or rapidly growing fibroids is an operation that, except in the hands of experienced operators, is not to be undertaken without considerable anxiety. The ligature of the broad ligaments and uterine arteries, the substitution of the intra- for the extraperitoneal stump, the complete removal of the whole organ by pan-hysterectomy and the remarkable results obtained make these the most reliable methods of dealing with these growths. Among the most recent suggestions for the removal of the annexa is that of Dr. Beatson of Glasgow, who had shown cases of cancer of the breast so advanced as to be inoperable, but in which he had removed the ovaries and tubes, with the result that in one case an apparently hopeless cancer of the breast was actually cured, while in the others a marked improvement took place. As another example of the potent influence of the ovaries upon the general economy, may be mentioned the accidental discovery and development of oöphorectomy for the cure of osteomalacia —a once thought hopeless disease. This is one of the most striking results of the development of gynecological surgery during the past decade. In the adoption of some of these more recent suggestions some of us may appear somewhat conservative, and others inclined to press matters too far and risk too much, yet the end we aim at is one—we can all take our part in that race whose goal is the alleviation of human suffering, whose prize may be shared by all.

The discussion of

DYSMENORRHEA

was introduced by PROFESSOR MURDOCK CAMERON in which he advocated dilatation for the spasmodic form and expressed his preference for graduated metal dilators. Dr. C. Martin thought rest was beneficial in nearly all cases, and hot vaginal douches in inflammatory cases, tampons of glycerin and ichthyol, and saline aperients. Morphin and alcohol should never be recommended. Bromids, belladonna, and cannabis indica he had found most useful, and viburnum a most excellent sedative. In

grave and incurable disease of the appendages their removal was indicated.

In the continuation of the discussion much stress was laid by others upon the rheumatic origin of dysmenorrhea, and the benefit of cycling. The uses of phenacetin, antipyrin, and electricity were extolled.

THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Forty-sixth Annual Meeting held at Harrisburg, May 19, 1896.

FOR the fourth time in its history, the Medical Society of the State of Pennsylvania convened beneath the shadow of the Executive Mansion in the attractive city of Harrisburg. This is literally true, for the sessions were held in the commodious chamber of the House of Representatives, which, as a convention hall, lacks but one quality, that of good acoustic properties. Thrice before, in 1868, 1877, and 1892, had the Dauphin County Medical Society extended to the State Association its cordial hospitality, and when once more the honor devolved upon it of welcoming the physicians of the State, every effort was made by the committee of arrangements and credentials, under the able chairmanship of Dr. W. T. Bishop, to excel in scientific interest and entertainment, the previous meetings in Harrisburg. That its efforts did not prove futile, all who were present will attest. Notwithstanding the unfavorable weather, which persisted throughout the three days of the convention, rendering the donning of overcoats a necessity, and materially increasing the organic (bacteriologic) constituents of Susquehanna River, the hearty spirit of good-will that existed, and the cordial hospitality of the citizens combined to render the meeting a success.

As heretofore the dominant features of the occasion were the social attractions, preëminent among which should be mentioned the reception tendered by Governor and Mrs. Hastings at their private residence on Wednesday evening, the 20th. Assisted by Private Secretary and Mrs. Beibler, the Governor received his professional visitors in the red room of the mansion, while Froelich's orchestra, stationed in an alcove, rendered choice music. The reception on Tuesday evening, at the Pennsylvania State Lunatic Asylum, was preceded by a charming tally-ho ride from the Commonwealth Hotel, and the visitors were welcomed by the superintendent, Dr. H. L. Orth, and the trustees of the institution. The president, Colonel Louis W. Hall, delivered a short address, which was eloquently responded to by Dr. T. D. Davis of Pittsburg. The receptions by the Dauphin County Medical Society on Thursday evening, at the Commonwealth Hotel, and on Wednesday noon by the Board of Managers of the Harrisburg Hospital, were well attended and much appreciated.

A notable feature of the convention was the celebration of the centennial of the discovery of the vaccine virus by Dr. Edward Jenner, which took place on Friday morning at Marietta. The discovery was completed May 14, 1796, but the celebration was timed to give the State Medical Association an opportunity of participating in the exercises, and, at the same time, of inspecting the vaccine farms of Dr. H. M. Alexander, at Marietta. These farms are considered the greatest of their kind in the world, and it was there the celebration took place. Fully three hundred people were present, and they were welcomed in an address by Colonel D. B. Case of Marietta. Dinner was served after an inspection of the farms, and was presided over by Dr. W. T. Bishop of Harrisburg. Toasts were responded to by Dr. W. M. Welsh, and Dr. E. W. Holmes of Philadelphia; Dr. M. R. Richards of New York; Professor E. O. Lyte, principal of the Millersville State Normal School; Dr. Rahler of Harrisburg, and Dr. H. W. Alexander. Literary and musical exercises followed.

DESCRIPTION OF THE FARMS.

The Lancaster County vaccine farms, adjoining Marietta, were begun on a modest scale by Dr. Alexander, and have grown within a decade to be the greatest of such establishments in the world, over six million points, besides crusts and lymph tubes, being shipped in a year. Besides these farms, Dr. Alexander has a similar place at Evansville, Pa., containing 167 acres.

On the Marietta farms, the stables have a perfect system of heating, ventilation, and sanitation, the floors being concrete and easily flushed into six tile sewers. All the stall floors are slightly raised. The preparing and finishing stables are divided into several sections. In one, newly received cattle are examined, and registered if the tests applied to discover the existence of disease are favorable. Passing another stable, where they are groomed and fed, they finally reach the incubation stable, as needed. The capacity of these stables is five hundred head, all young heifers, secured in Lancaster county.

There are six tables in the operating-room, which is finished in hardwoods and flushed three times daily when in use. The heifer to be vaccinated is swung upon the table by an ingenious windlass contrivance, and then carefully vaccinated, usually upon the inner portion of the limbs, where, Dr. Alexander claims, the vesicles have the best development.

Long experience is necessary in determining the proper time for removing the lymph, the subject being placed again upon the operating table when this is done, and before the crusts are removed, the parts about them are carefully cleaned. When the lymph begins to exude, like drops of perspiration, it is gathered on small brushes and afterward applied to the ivory points, which are fastened in bunches of fifty. Afterward they are inspected at the packing establishment. Seed-points are collected in a similar manner, but from special heifers. Liquid lymph is removed by flowing it from the blade of a scalpel into vials, and is mixed with glycerin to preserve it. The points are placed in sterilizing jars and then kept in a refrigerator. When hardened they are packed and are ready for shipment.

The session opened on Tuesday morning at nine o'clock, the Society being called to order by the president, Dr. William S. Foster of Pittsburg, with nearly three hundred delegates in attendance. Prayer was offered by Rev.

Dr. Ellis N. Kremer, pastor of the Salem Reformed Church, after which addresses of welcome were delivered by Governor Hastings, City Solicitor Leitz, and W. T. Bishop. Much important business was transacted, including the appointment of a committee of three (Drs. H. S. McConnell, New Brighton; John J. Buchanan, Pittsburg, and G. B. Sweeney, Pittsburg) to take measures to prevent the bill now before Congress, providing for the abolition of vivisection, from becoming a law. The report of Secretary Atkinson showed a steady growth in membership during the past year, and the organization of medical societies in Snyder, Erie, Bedford, Tioga, and Juniata counties. The question of amending the by-laws by authorizing the publication of the transactions of the society in journal form, was laid over until the next annual meeting. Dr. Lemoyne, chairman of the committee on scientific business, announced that sixty-four papers had been secured for the meeting, all of them of practical interest and special merit.

The nominating committee, composed of one member from each county delegation, made its report on Wednesday afternoon. Pittsburg was selected as the next place of meeting, and Dr. T. D. Davis of that city, made the statement that the medical fraternity in Allegheny County will endeavor to make that the most successful convention in the Society's history. The following officers and delegates were chosen:

President, Dr. E. E. Montgomery, Philadelphia; first vice-president, Dr. C. S. Shaw, Allegheny; second vice-president, Dr. F. B. Ball, Clinton; third vice-president, Dr. T. M. Livingston, Columbia; fourth vice-president, Dr. A. C. Wentz, York; secretary, Dr. W. B. Atkinson, Philadelphia; assistant secretary, Dr. Adolph Koenig, Allegheny; treasurer, Dr. G. B. Dunmire, Philadelphia.

Members of judicial council—Dr. M. A. Rhoads, Berks; Dr. John H. Pachard, Philadelphia; Dr. John Curwen, Warren.

Committee on publication—Dr. Edward Jackson, chairman; Dr. H. A. Hare, Philadelphia; Dr. G. W. Guthrie, Luzerne; Dr. J. H. Wilson, Beaver; Dr. D. W. Nead, Dauphin.

Censors, First District—J. W. Walk, Philadelphia; S. P. Bartleson, Delaware; James Fulton, Chester.

Second District—J. B. Walker, Bucks; E. M. Green, Northampton; Wm. B. Erdman, Lehigh; Wm. L. Kutz, Carbon.

Third District—J. K. Weaver, Montgomery; W. Murray Weidman, Berks; A. F. Branson, Schuylkill.

Fourth District—T. M. Livingston, Columbia; H. McGowan, Dauphin; H. O. Qaris, Perry; William M. Guilford, Lebanon; A. M. Smith, Snyder.

Fifth District—W. F. Bacon, York; John Montgomery, Franklin; R. P. Coons, Cumberland.

Sixth District—Crawford Irwin, Blair; S. C. Stever, Huntingdon; D. M. Crawford, Juniata.

Seventh District—J. S. Troxell, Cambria; H. M. Latchey, Somerset; A. H. Hershberger, Mifflin; J. W. B. Kamerer, Westmoreland; J. T. Cess, Indiana.

Eighth District—Samuel Ayers, Allegheny; J. B. Donaldson, Washington; W. S. Throckmorton, Greene.

Ninth District—S. D. Bell, Butler; H. M. Shallenberger, Beaver; J. W. Marston, Mercer; J. F. Ritchey, Venango; R. S. Wallace, Clarion.

Tenth District—W. B. Hazeltine, Warren; A. Mulhaupt, Elk; C. A. Belmer, Jefferson; A. M. Straight, McKean; Daniel L. Davis, Erie; W. D. Hamaker, Crawford.

Eleventh District—J. L. Henderson, Clearfield; G. F. Harris, Center; G. F. Bell, Lycoming; R. B. Watson, Clinton; W. D. Vedder, Tioga.

Twelfth District—P. C. Newbaker, Montour; L. B. Kline, Columbia; W. G. Weaver, Luzerne.

Thirteenth District—S. M. Woodburn, Bradford; C. C. Halsey, Susquehanna.

Delegates to American Medical Association—J. J. Buchanan, Allegheny; W. B. Ulrick, Delaware; H. X. Baubreck, Franklin; G. B. Dunmire, Philadelphia; W. E. Sweiler, Cumberland; William Mickelsan, Venango; W. B. Logan, Cambria; W. C. Simpson, Beaver; Arthur C. Wheeler, Erie; W. S. Foster, Allegheny; H. G. McCormick, Lycoming; A. H. Habenstadt, Schuylkill; Robert G. Furst, Clinton; W. S. Wilson, Mifflin; Thomas Milliken, Greene; A. E. Snyder, Susquehanna; E. H. Coover, Dauphin; W. D. Tweedle, Carbon; J. T. Klinedinst, York; W. Murray Weidman, Berks; J. H. Wilson, Beaver; J. W. Groff, Montgomery; Alex. Craig, Lancaster; J. W. Morrow, Forest; Evan O'Neill Kane, McKean; H. G. Creitzman, C. L. Stevens, Bradford; G. G. Harman, Huntingdon; B. H. Detweiler, Lycoming; R. H. Short, Cumberland; Willis M. Baker, Warren; W. S. Brenholtz, Lancaster; W. S. Langshore, Luzerne; F. F. Davis, Venango; J. W. Sheetz, Northumberland; J. R. Care, Montgomery; E. R. Gardner, Susquehanna; John Fry, Blair; C. M. Strickler, Warren; W. R. Palmer, Elk; Laura J. Dice, York; Ellen Brown, Delaware; I. P. Klingensmith, Indiana; D. H. Bergey, Montgomery; John Montgomery, Franklin.

Delegates to Pan-American Medical Congress—J. M. Anders, Philadelphia; Ernest La Place, Philadelphia; W. T. Bacon, York; R. S. Ramsay, Franklin; A. M. Miller, Lancaster; E. M. Carson, Montgomery; T. D. Davis, Venango.

Delegates to Maryland Medical Society—C. C. Hummel, Cumberland; W. Murray Weidman, Berks.

In the scientific matter of the meeting there would seem to be as worthy of special mention, the discussions on typhoid fever, antitoxin, and alcohol; the magic-lantern lecture on certain forms of the malarial parasite, by Dr. Judson Doland of Philadelphia, the address of the president, Dr. William S. Foster of Pittsburg, on the relations existing between the profession and the public, and the address on surgery, hygiene, and obstetrics, by Drs. John J. Buchanan of Pittsburg, J. W. Moore of Easton, and Israel Cleaver of Reading.

J. C. LANGE, M.D., of Pittsburg, read a paper on

THE ANTISEPTIC FACTOR OF THE TREATMENT OF TYPHOID FEVER.

He claimed that if the antiseptic factor be properly employed, it may prevent the necessity for symptomatic

treatment. External antisepsis consists in the use of bichlorid baths and clean clothing. Orificial antisepsis includes rectal and vaginal washes of carbolic-acid solution, and mouth-washes of boracic acid and potassium chlorate. The ears also should be rendered aseptic. Intestinal antisepsis includes the use of guaiacol and iodoform, while general or constitutional antisepsis may be obtained by the administration of one-eighth grain of calomel thrice daily. No other treatment is indicated unless hemorrhage occurs, when opium will be required. Lange claimed that this course of treatment will prevent the ocurrence of secondary infection, which is commonly known as the complications of typhoid fever.

H. S. McConnell, M.D., of New Brighton, read a paper on

ELIMINATION, STARVATION, AND ANTISEPTICS IN THE TREATMENT OF TYPHOID FEVER.

He urged the importance of the starvation treatment of the disease. His paper was based on the fact that the hydrochloric acid and pepsin are greatly diminished in amount during the disease. He would feed mainly on hot water.

T. P. Simpson, M.D., of Beaver Falls, spoke of

THE USE OF ALCOHOLIC STIMULANTS IN TYPHOID FEVER.

He stated that the abuse of alcohol in this disease has done more harm than good. The routine use of alcohol is to be deprecated. Many cases of the fever require none whatever. Its excessive use induces gastric catarrh. It is useful only in the small quantity that increases the gland secretion and does not overstimulate. If employed, whisky is the best form for the purpose.

In the discussion of these papers, Dr. McCormick of Williamsport, protested against the use of opium in hemorrhage. There are remedies that will not bind the bowels that are far superior to it.

Dr. Fowler of Marionville, emphasized the fact that a certain amount of fever in the disease is curative, as suggested by Professor Hare, and this must be expected and should not be checked.

Dr. T. D. Davis of Pittsburg, remarked that typhoid fever is greatly modified by the district in which it occurs; therefore, the treatment must vary according to the type of the disease presented. Guaiacol will not act in that form of the fever in which there is no malarial element.

In reply, Dr. Lange stated that he would favor the use of morphin in hemorrhage. He objected to the use of the ice-bag, and would prefer to use heat to dilate the efferent vessels and thus control the bleeding. The action of ergot on the blood-vessels is not very definite, save on those of the cord and brain. In this disease the source of the hemorrhage, whether capillary or venous, is not known. Other remedies than morphin fail to reach the spot in time.

Dr. McConnell urged that hemorrhage is the best indication that the bowel is not aseptic, and should suggest the use of intestinal antiseptics.

Edwin Rosenthal, M.D., read a paper on

THE REDUCTION OF THE PERIOD OF INTUBATION BY SERUM TREATMENT OF LARYNGEAL DIPHTHERIA.

He stated that he wished to prove that intubation is preferable to tracheotomy. He is in the habit of having his tubes regilded after each operation, so that the patient practically has a new tube. In European cases, the reduction of the period of intubation has been from eighteen to twenty-five hours; in the American cases, the reduction is from sixty to seventy-five hours. Under the serum treatment, no alarming symptoms appeared.

Dr. W. M. Welch, of the Municipal Hospital of Philadelphia, stated that his experience was not in accord with the results of Dr. Rosenthal's paper. The only way to prove that the tube in cases of antitoxin treatment can be removed earlier than in the non-antitoxin cases, is to make the experiment by removing the tube in both classes of cases daily, and this has not been done. He has tried to remove the tube at an earlier period, but was compelled to return it. The patient who wore the tube the longest (three months) in Philadelphia, was treated with antitoxin. During this time he coughed up the tube at least seventy times, but was compelled to have it returned.

Dr. T. D. Davis of Pittsburg, claimed that much depended upon how much antitoxin was used, when it was used, and how. He has seen good results follow its employment. He has never seen the membrane persist forty-eight hours under the use of antitoxin.

Dr. Rosenthal, in reply, stated that he had used the remedy in 134 curative cases. It is necessary to know how to use it, and a good preparation must be employed. He uses Mulford's antitoxin. After the membrane disappears, he waits one day and then removes the tube. If the patient improves after the first dose, he increases the dose; thus, if the first dose was 1–1000, the second should be 2–1000, and the third 4–1000. Billings has proved that antitoxin does not alter the blood. He has never known harm to follow the use of the antitoxin.

James Fulton, M.D., of New London, read a paper on

ALCOHOLIC STIMULANTS IN THE TREATMENT OF DISEASE.

This excited an animated discussion, which was participated in by Drs. Hare, Borland, Flick, and Lemoyne. The value of the drug depends upon its judicious employment in well-selected cases; its routine use is to be deprecated, and the dose can only be determined according to the requirements of the case.

E. B. Borland, M.D., of Pittsburg, read a paper on

THE PREVENTION OF TUBERCULOSIS.

He stated that the convalescence of typhoid fever, measles, and whooping cough, offer the debility and lesions necessary for the development of tuberculosis. The alimentary tract in children is the most important avenue of tuberculous infection, and the respiratory tract in adults, dental instruments, communion cup, drinking-vessels, kissing, and the like, are important sources of infection. Fifteen per cent. of milch-cows are tuberculous, and these should be destroyed as soon as discovered; all milk should be boiled before using. Expectoration

upon floors and sidewalks should be made a misdemeanor. Cuspidors containing straw, saturated with 1–250 mercuric-chlorid solution should be placed in all public places. Latent tuberculosis needs no precautions.

DR. LEMOYNE believes that the attitude of the public upon this important question is a disgrace to civilization.

DR. E. O. KANE of Kane, regards the chief predisposing influence in the production of tuberculosis as heredity, and this hereditary tendency is largely increased by the debilitating influence of inherited syphilis, which affects from one-twentieth to one-tenth of the race.

DR. L. FLICK of Philadelphia, does not believe that there is any relationship existing between syphilis and tuberculosis. It is doubtful, he stated, whether tuberculosis can be contracted in utero, and there is no transmission of the disease from mother to child.

DR. J. M. ANDERS of Philadelphia, did not agree with the last statement. In very rare cases, the tubercle bacillus may be found in the placenta, and in the tissues of the newborn infant. There may be late hereditary tuberculosis as well as late hereditary syphilis.

DR. JAMES TYSON of Philadelphia, heartily endorsed the views advanced by Dr. Anders.

DR. E. LAPLACE of Philadelphia, stated that tuberculosis appears in various forms in different ages of the individual. It first develops as bone-tuberculosis; later as gland-tuberculosis; later still, as meningeal tuberculosis, and finally, as pulmonary tuberculosis, which is the refinement of tuberculosis. The tendency to the disease is born with the individual, but this is only the minor consideration. Reduce the condition of the body-vitality and the disease may readily be developed. This has been demonstrated upon the brown rat which will not contract the disease under normal circumstances.

J. M. ANDERS, M.D., of Philadelphia, contributed an article on

SOME THERAPEUTIC USES OF GUAIACOL.

He stated that this drug was of service in three groups of cases: (1) In certain febrile affections, acute and chronic, especially typhoid fever and the pneumonias. McCormick has used it more than eight hundred times in these diseases with excellent results. Rigors indicate the administration of too large a dose. Anders has had decided rigors with high fever follow in the two cases of this disease in which he has used guaiacol. He has, however, had excellent results in intestinal catarrh, with fermentative changes. Fever, dependent upon local inflammation, is reduced much more readily by guaiacol than that dependent upon general causes. He has used it in pulmonary tuberculosis, but has abandoned it on account of the sweating produced thereby. (2) Afebrile diseases, as myalgia and neuralgia, eleven out of twelve cases of neuralgia were successfully treated by him by guaiacol used externally. (3) Acute, subacute, and chronic rheumatism. In this class of cases guaiacol relieves pain, but does not control the inflammatory action.

E. E. MONTGOMERY, M.D., of Philadelphia, read a paper on

THE TREATMENT OF PELVIC INFLAMMATORY CONDITIONS THROUGH VAGINAL INCISIONS.

He claimed that both the vaginal and abdominal routes have their place in pelvic surgery. Pelvic inflammation may extend through the lymphatics and blood-vessels, although it commonly extends from the uterus to the tubes. The offending cause may be removed per vaginam, and even a cure result with the minimum danger to the patient. The cervix uteri is often the seat of disease, and contains rich lymphatics. The vaginal incision affords a ready means of excision of the cervix and uterus, and its appendages. Pryor has suggested an incision in the posterior fornix for retroflexion with adhesions. The latter are broken up, and the uterus held forward by a tampon placed back of the organ, while another is placed in front of the cervix in order to push this back. Baldy objects to the vaginal route as unsurgical; the wound is foul and the method objectional in every sense. Noble was not in accord with Montgomery as to the relative value of the vaginal route as compared to the abdominal. Better results follow the latter. A larger percentage of complete operations can be done from above. From above fewer complications follow, such as injuries of the ureters and vessels. He would prefer to operate from below in puerperal and old neglected cases.

JOHN J. BUCHANAN, M.D., of Pittsburg, made an address upon

SOME IMPORTANT PROGRESS IN SURGERY.

In speaking of appendicitis, he recommended the removal of the appendix in the earliest stage of the disease. Recurrent and chronic cases should be operated upon between the attacks. There are two periods in which the appendix may be safely removed, namely, at the beginning, and in the intervals. In difficult cases of fracture in which reduction is impossible, opening the wound and suturing or pegging the fragments together is advisable. Detached fragments of bone should not be removed. The process of repair is delayed in operative cases by the absolute immobility of the fragments, which hinders the formation of callus. He advised the infusion of many quarts (six or more) of saline solution directly into the veins when much loss of blood has occurred before or during operation. If required, the infusion should be repeated once or twice.

J. M. BALDY, M.D., of Philadelphia, offered a paper on

PELVIC PERITONITIS FROM THE STANDPOINT OF THE GENERAL PRACTITIONER.

He said that in chronic disease of the tube with acute exacerbations, therapeusis will probably cure the symptoms, but not the original condition of the tube, which persists as a constant menace to the patient. A diagnosis of the diseased condition is very important in influencing the prognosis. The medical treatment of peritonitis is routine, and not influenced by the cause of the disease. At times it is important to relieve the acute symptoms before the operation is performed, and the physician should be able to do this. Rest, depletion, and relief of pain are the indications of treatment. Sexual rest is secured by a large, soft wool tampon. Depletion may be accomplished by scarification or leeching of the cervix, or better by saline purges (Epsom salt) in full doses. If this be re-

jected by the stomach, calomel may be exhibited in grain doses, repeated as required, or an enema of soapsuds will answer. In severe pain, from one-sixth to one-fourth grain of morphin should be given after free purgation. The depletion should be followed by vaginal douches twice daily. Antipyretics are not required. Noble remarked that the abdomen is apt to suppurate after counter-irritation. He would not use douching during the height of the peritonitis. Codein with hyoscyamus will relieve pain without locking up the bowels as morphin will do. Massey recommended the icebag for the pain, and Lemoyne prefers for catharsis sodium sulphate, which is a diuretic as well as a cathartic.

Carl Seiler, M.D., made remarks on

PERFORATION ON THE NASAL SEPTUM.

This, he said, is not a rare condition. Perforation of the lower or cartilaginous portion of the septum is rarely syphilitic, but usually "chronic traumatic," that is, due to the repeated removal of scabs, due to the pressure exerted by a spur or by an hypertrophied turbinated bone. A perforation here may also be caused by abscesses of Jacobson's organ, or by pressure exerted by foreign bodies, or by unskilful surgical interference. To repair the condition, a plastic operation is preferable. A hard rubber obturator has been successful in some cases. In operating, the flap is taken from the cartilage above or below, and secured by fine silk sutures.

William H. Harrison, M.D., of Harrisburg, read a paper on

THE PATHOLOGY OF THE BLOOD OF THE INSANE.

He said that a tendency to slow coagulation is a rule in insanity, although in acute cases there is noted at times an increased tendency to clot. By the condition of the blood the diet may be regulated and corrected. Harrison emphasized the value of the hematokrit, hemomelis, and other blood-examining instruments in the study of insanity. There is a marked diminution in the number of the red corpuscles in melancholia, and this is especially marked in those cases in which forced bleeding is necessary. Tyson regards this as a new field of study. He spoke of the insanity following typhoid fever, which he considered as a variety of insanity of exaltation.

G. E. Shoemaker, M.D., of Philadelphia, read a paper on

THE FIBROID UTERUS—WHEN AND HOW TO OPERATE.

He said that small tumors call for extirpation when local pressure and bleeding are present, the flow lasting over seven days. If drugs be employed, hydrastin and ergot may be given. If the tumor occupies the lower segment of the uterus in pregnancy, hysterectomy should be done in the early months. All tumors affected with suppurative inflammation, or that are growing rapidly, should be removed. Hysterectomy should not be considered in advanced phthisis. Kidney disease, however, is not a contraindication. A small tumor may be shelled out in some cases; in other cases, hysterectomy is advisable by the abdominal route, dropping the stump. Noble advised prompt operation. It is only exceptional cases that do not require operation.

Henry Beales, Jr., M.D., of Philadelphia, read a paper on

THE CLINICAL STUDY OF DIGITIN.

This is a yellow crystalline substance, quite distinct from digitalin. It is indicated in all diseases in which digitalin is required. It is pronounced by Merck to be therapeutically inert, but if given in doses up to one-half grain three or four times daily, it is useful. The drug does not irritate the digestive tract as does digitalin. Dropsies disappear almost immediately from the direct stimulating action of the drug upon the cardiac ganglia and centers governing the action of the heart. Passive cerebral hyperemia, with vertiginous symptoms indicating threatened apoplexy, may be relieved by proper doses of digitin. The power of the drug to influence capillary tonus is marked. It restores nutrition by stimulating metabolic action in the cell-structure. It is a very reliable drug.

T. D. Davis, M.D., of Pittsburg, presented a paper on

THE IRRITABLE UTERUS OF PREGNANCY.

He stated that a common symptom of the condition is pain variously located, appearing in the sacral region, in the regions of the ovaries, or in the uterus. It is often severe enough to disturb sleep. The condition is a true neurosis, and in its treatment the free use of bromids is necessary. The patient should not be permitted to confine herself to bed.

J. W. Moore, M.D., of Easton, delivered an address on

HYGIENE.

He said that one-fifth of all children, dying in the first year, perished from tuberculosis of the digestive tract, produced by the milk ingested. He believes that the theory of the contagiousness of tuberculosis founded on statistics covering a limited area of a community, and taken during a limited number of years, is not a satisfactory nor a correct one. He thinks that our knowledge of bacteria is still very meager, and is not in accord with the enthusiasm of the age.

F. S. Pearce, M.D., of Philadelphia, offered a paper in a clinical report on

THE USE OF TESTICULAR FLUID INJECTIONS,

Covering a department of the subject of organotherapy. Five hundred injections were made by him of Brown-Sequard's fluid in thirty males and ten females, suffering from locomotor ataxia, sclerotic changes in the cord, neurasthenia, and the like. From twenty to thirty minims formed the average dose injected. The frequency of the injection should be every other day. Nausea, vomiting, and diarrhea indicate an overdose. Improvement was noted in nervous diseases of a chronic nature, and consisted in a general stimulation as well as an increase in the sexual sense.

R. W. Stewart, M.D., of Pittsburg, spoke on

THE TECHNIC OF SUPRAPUBIC CYSTOTOMY.

He emphasized the danger of opening the peritoneal cavity. By the technic offered, he showed that it need not be involved. He feels for the upper border of the symphysis, and introduces the knife at this point, hugging the inner surface of the pubic bone. The operation can be done on an empty as well as on a distended bladder without any danger of involving the peritoneum.

MARY MCC. WENCK, M.D., of Sunbury, read a paper on

THE HYGIENE OF PREGNANCY.

She dwelt upon the influence of the mental condition of the mother upon the fetus. If she be irritable during her pregnancy, the child will be the same, and she claims this fact from a study of one thousand cases in her own practice. Clothing, food, exercise, and muscular tonics, including friction and massage, are important elements in the hygiene of gestation.

Other papers of note were those by Drs. B. F. Baer of Philadelphia, on "Hysterectomy for Retroperitoneal and Intra-ligamentous Uterine Fibroid Tumors;" E. W. Holmes of Philadelphia, on "Cerebral Concussion and Compression with Report of a Case of Trephining;" Ernest Laplace of Philadelphia, on the "Surgical Treatment of Insanity, with Report of Cases," in which he described his operation of craniectomy; Lewis J. Lauterbach of Philadelphia, on "Phono- and Pneumo-massage for Suppurative Disease Deafness;" Anna M. Fullerton of Philadelphia, on "Records of Work in the Woman's Hospital of Philadelphia;" and S. S. Fowler of Marionville, on "A Practical Way for the Increase of Membership." A number of papers were read by title.

CIRCULAR OF INFORMATION FROM THE NEW YORK CITY HEALTH DEPARTMENT.

THE IMPORTANCE OF BACTERIOLOGICAL EXAMINATIONS IN THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.

THE symptoms of incipient pulmonary tuberculosis are few, not marked and not uniform. They are frequently not sufficient in number or importance to attract the attention of the affected individual, and their significance is often not recognized by physicians, as there are other conditions which closely resemble incipient pulmonary tuberculosis.

Tuberculosis results from the reception into a susceptible system of tubercle bacilli. These are usually drawn in with the air inspired, and find lodgment in some portion of the respiratory passages. There they increase in number, when conditions favorable for their multiplication exist, and by their growth set up an inflammation which becomes evident in the formation of new tissues, the so-called tubercle. The inflammatory changes are usually at first very slight, and the effects entirely local. Moreover, in this early stage there is a marked tendency to a localization and restriction of the process and to an entire recovery. Many persons get well untreated. In such cases the tubercles are gradually replaced by fibrous tissue, and the bacilli die or are rendered harmless. At this time, *i.e.*, when a patient has tuberculosis, but when the disease is confined to a small, sharply circumscribed area, there is the best opportunity for successful treatment.

On the other hand, in a large percentage of the unrecognized and neglected cases, recovery does not take place, but the tubercular process extends; new tubercles form, the old ones become necrotic, and there is a coalescence of separate foci of infection, forming large areas of disease, till a great part of one or both lungs is affected. At the same time, the bacilli in their growth form poisons, which are absorbed by the system, and in the diseased or necrotic tissues other bacteria are deposited, producing the so-called mixed infection.

The disease has now assumed a far more serious aspect, is easily recognizable, and constitutes what is commonly called consumption. With few exceptions, this progresses to a fatal termination. The classical symptoms commonly assigned to early tuberculosis, *i.e.*, persistent cough with expectoration, loss of appetite and weight, hemoptysis, are really signs, in most instances, not of the incipient affection, but of the advanced disease. In the early stage, a positive diagnosis is possible only when tubercle bacilli are found in the expectoration. It is an impression commonly held that the bacilli are not found unless the disease has advanced to a point at which the signs presented on a physical examination are themselves almost conclusive. Such, however, is not the case; bacilli are not infrequently found in the expectoration when the physical signs are indicative only of a slight bronchitis, or when there are absolutely no physical signs obtainable. When signs of consolidation are present, the affected area is always considerable, and always far greater than would be inferred from the evidences obtained on examination. It is, therefore, of supreme importance that the diagnosis should be made at the earliest possible moment. The expectoration should be examined early, and if bacilli are not found immediately, should be examined repeatedly in every case of doubtful diagnosis. All cases, also, in which there is a cough, with or without expectoration, persisting for more than a few weeks, and all cases in which there is unexplained pallor, loss of appetite, languor, or loss of weight (general debility), even if the cough appears to be almost entirely absent, should be considered cases of doubtful diagnosis, and bacilli should be sought for in the expectoration.

In conclusion, emphasis should be laid upon the following clearly demonstrated facts:

First.—Incipient tuberculosis tends to recovery.

Second.—Advanced tuberculosis, with or without mixed infection, tends to a fatal issue.

Third.—In all coughs which last more than a few weeks, tuberculosis is to be suspected as a cause.

Fourth.—Successful treatment and prophylaxis demand the earliest possible diagnosis.

Fifth.—The positive diagnosis of incipient pulmonary tuberculosis properly so-called is possible only when tubercle bacilli are found in the expectoration.

Sixth.—Repeated examinations of the expectoration are frequently necessary to demonstrate the presence of the

tubercle bacilli in incipient cases of pulmonary tuberculosis.

THE USE OF MALLEIN FOR THE DIAGNOSIS OF GLANDERED HORSES. 1896.

The Health Department of New York City is prepared to furnish mallein for the diagnosis of glanders in horses. This is prepared by Nocard's method, and is furnished in vials containing a single dose of 2½ c.c.

In order that accurate results may be obtained in all cases where mallein is employed for the diagnosis of glanders, the following directions should be carefully followed.

First.—The temperature of the animal to be tested should be taken three times a day for three days previous to the injection, to determine the mean temperature.

Second.—The animals to be tested should be protected against sun, rain, or wind, as these influences may occasionally cause a rise of temperature of one or two degrees or more, independent of the action of mallein.

Third.—On the day of injection, the temperature should be taken every two hours from early morning until late at night, and during the two succeeding days it should be taken three times a day.

Fourth.—The injection should be made into the shoulder, and the skin should be previously washed thoroughly with soap and water and then with some antiseptic solution, such as lysol 2 per cent., carbolic acid 5 per cent., or bichlorid of mercury 1–1000. Care should be taken to carefully sterilize the needle of the syringe after each injection, or, better, to use separate needles, if healthy and suspected animals are being inoculated at the same time. The animals supposed to be healthy should be first injected, and the needle (if it is necessary to employ the same needle) carefully sterilized by heating to a red heat or boiling in a 1 per cent. soda solution after the injection of each suspicious animal.

Fifth.—The thermometer should be sterilized in 5 per cent. carbolic acid solution after the temperature of each horse is taken.

Following an injection of mallein in a glanderous horse, there will be a general reaction, with a rise of temperature and a local reaction. The temperature usually begins to rise three to four hours after the injection, and reaches its maximum between the tenth and twelfth hour. Sometimes, however, the hightest point is not reached until fifteen or eighteen hours after the injection. This elevation of temperature is from 1½ to 2° C., or even 4° C. above the normal mean temperature (*i.e.*, 2.7 to 7.2° F.).

In a healthy animal the rise of temperature, as a rule, amounts to only a few tenths of a degree, but it may reach a degree C. (=1.8° F.), or a little more. The rise of temperature, however, should always be considered in connection with the general and local reactions.

In a glanderous animal, after an injection of mallein, the general condition is more or less profoundly modified. The animal has a dejected appearance; the countenance is pinched and anxious; the hair is rough and on end; the flank is retracted; the respirations are rapid; there are often slight or decided rigors; the appetite is gone. These symptoms vary greatly in different animals, but are never completely lacking.

In healthy animals the general symptoms do not occur.

The local reaction around the point of injection in a glanderous animal is very marked. A few hours after the injection, there appears at this point a large, warm, tense, and very painful inflammatory swelling, and running out from the contour of this swelling will be seen hot sensitive lines of sinuous lymphatics, directed toward the neighboring lymphatic nodes. When the injection has been made aseptically, this swelling never suppurates. It, however, increases for twenty-four to thirty-six hours, and persists for several days, not disappearing entirely until after eight or ten days.

In healthy animals, at the point of injection, mallein produces only a small edematous tumor, slightly warm and sensitive, and the edema, instead of increasing, diminishes rapidly and disappears entirely in less than twenty-four hours.

It is important to remember that the phenomena produced by mallein in glanderous animals persist for a long time, the prostration continuing for from twenty-four to forty-eight hours, and the temperature remaining above normal.

If in any case the reaction obtained is only sufficient to cause the suspicion of glanders (*e.g.*, a rise of temperature of 0.8 to 1.1° C., or 1½ to 2° F.), the injection of mallein should be repeated at the end of four or five days. Healthy animals seem to acquire an immunity to mallein, while glanderous animals will still react.

Certain diseases, *e.g.*, parotitis, often cause marked oscillations of temperature. When testing horses affected with such diseases, it should be noted after the injection whether the rise of temperature is persistent, and whether the general and local reactions are present. It is always better, however, when possible, to avoid injecting mallein in horses which already show an elevation of temperature.

In acute glanders accompanied with high temperature, it sometimes happens that after an injection of mallein the temperature does not rise a full degree. In other diseases, where the temperature is already high, there will generally be no elevation at all of the temperature, and there may even be a depression.

The Health Department of New York especially requests that all veterinary surgeons who use mallein will forward full reports of the results obtained.

By order of the Board of Health.

CHARLES G. WILSON, President.

EMMONS CLARK, Secretary.

REVIEWS.

IN SICKNESS AND IN HEALTH: A Manual of Domestic Medicine and Surgery, Hygiene, Dietetics, and Nursing. Edited by J. WEST ROOSEVELT, M.D. Pp. 991. New York: D. Appleton & Co., 1896.

BUT a small part of this large and elegant volume is

written by Dr. Roosevelt. A chapter or a section is furnished respectively by Drs. Geo. W. Crary, S. T. Armstrong, A. B. Johnson, Wm. P. Northrup, F. W. Jackson, Samuel W. Lambert, Frederick Peterson, and H. A. Griffin, and by Messrs. Josiah Royce, Frederick S. Lee, and Joseph H. Seers, and by Miss Anna C. Maxwell.

Our disapproval of a manual of *Domestic* Medicine has been stated very positively in these columns. We consider the rational practice of medicine as based on a diagnosis, and we fail to understand how the layman is to be invested, by the purchase of this book, with the faculty of entire comprehension of disease. The publishers distinctly state that the book was prepared for household use and "for the unprofessional man and woman." We therefore condemn it, in large measure, while we approve very heartily of the instruction of the layman in hygiene, dietetics, nursing, and "first aid."

The chapters on Physiology, Outlines of Psychology, and Physical Training are admirable and of great value. So also are the sections on Nursing of the Sick, by Miss Maxwell, and on Nervous and Mental Diseases, by Dr. Peterson. In the latter section the questions of heredity, psychic, and somatic, of nervous stress and of alcoholic inebriety are treated in a lucid, useful, and interesting way. While giving the reader the information he ought to possess, Peterson skilfully avoids suggesting treatment, and refers him to a physician.

It is with the parts of the book that suggest and encourage self-prescribing and lay "doctoring" that we find grave fault. Fronting page 646 is an illustration of a typical case of scarlet fever and one of a typical case of measles. Of what possible use are they to laymen? Suspecting either of these diseases, the possessor of this dangerous work will naturally turn to these lithographs, and, finding that the case in hand does not show the characteristics of either picture, will decide that the child is safe. Probably contagion will go on unchecked, the mother's anxiety having been allayed; for has she not, in effect, consulted the skilful Dr. West Roosevelt by looking at the pictures? But, to do the work full justice, she has a safeguard in a sentence on page 647, where we read: "In a general way, the history of the behavior of the eruption of typical scarlet fever conforms to the old rhyme: 'One to begin, two to make show, three to make ready, and four to go!'" How lucid and helpful!

On page 668 we find this sentence: "Colchicum used during an acute attack (of gout) almost always checks it within twenty-four hours." While the policy of checking it is deprecated, nothing is said about the danger of the drug. No caution is given against its use, unless prescribed by a physician. It is simply put into the hands of the domestic dabbler in empiricism to use as he will. Better it were a knife!

The author of the section entitled "Medicines and Treatment" has a curious notion of his reader's intelligence, for he puts in quotation marks the expressions, "ride the wheel," "nervousness," "virus," and "cow-pox," yet omits the marks in the case of prophylactic, premonitory, etc. Much of his advice is dangerous, some of it is erroneous. On page 833 he says: "All diarrheas must be promptly checked." On the same page he savs "avoid night air" in malarious districts. What shall we breathe at night? The first medicine he recommends, in a long list which he considers suitable for the family chest, is morphin sulphate, in tablets of one-eighth of a grain each. "Dose for an adult, one tablet" (page 835).

The third drug he suggests is tincture of aconite, in tablets, to be labeled: "For fever. For sore throat. Dose for an adult, one tablet every half hour, until tongue and lips feel numb"! At the close of the paragraph he adds: "In long-continued and low fevers, and if exhaustion is present, as shown by a weak pulse, it will do harm." What does the laity understand by a "long-continued" or a "low" fever? On page 840 he says: "True chills and fever occurs in attacks at the same time every day, or every second (rarely every third) day." Is that error merely typographical? Speaking of the fashion of calling every ache a symptom of "malaria," and using quinin for it, he says (page 840): "Fortunately, this error, though foolish and unscientific, is usually not productive of much harm." The aurists will assure the author of the contrary fact, that this indiscriminate quinin-dosing is productive of much harm. We commend, without reservation, the author's denunciation of the continuous use of coffee, and rejoice to see that he positively forbids it to "youth, nervousness, most diseases of the heart, some forms of indigestion, and in the bilious tendency." We echo his statement that chlorate of potash should never be used by the laity. We must take exception to his exhortation to the obese, when, in spite of the simple remedies which he suggests, they remain fleshy: "Be content, for nature intended it to be so." By a parity of reasoning we should disregard malignant tumors, tubercular joints, and cross-eyes.

But the most amazing advice that we have found in the book, during a hasty reviewal, is contained in the following sentence, quoted from p. 546. Dr. Johnson has described, very superficially, acute catarrhal inflammation of the middle ear, and adds: "The treatment consists of puncture of the drumhead, in severe cases, to let out the retained secretion, and of inflation of the middle ear through the Eustachian tube." This is advice upon which the "unprofessional man and woman" are to practice "domestic surgery."

Enough has been quoted to indicate the extent to which the book transcends the bounds of a proper "manual of domestic practice," and it remains but to praise the typography, the paper, and the presswork, which are of superior style and handsome appearance.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 25, 1896.

July 18.—Assistant Surgeon L. MORRIS detached from Indian Head Proving Ground, ordered home and granted one month's leave.

July 21.—Assistant Surgeon F. C. COOK, detached from treatment at the New York Hospital and ordered to proceed home.

Medical Director G. H. COOK, detached from special duty at Philadelphia and ordered to take charge of hospital there.

Medical Director D. KINDLEBERGER, detached from duty in charge of hospital at Philadelphia, ordered home and await orders.

Medical Inspector W. G. FARWELL, ordered to special duty at Philadelphia, attending officers.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXIX. NEW YORK, SATURDAY, AUGUST 29, 1896. NO. 9.

ORIGINAL ARTICLES.

ACUTE NASOPHARYNGEAL INFLAMMATION.

BY J. LEWIS SMITH, M.D.,
OF NEW YORK;
EMERITUS PROFESSOR OF DISEASES OF CHILDREN, BELLEVUE HOSPITAL MEDICAL COLLEGE; PHYSICIAN TO THE NEW YORK FOUNDLING ASYLUM AND TO THE INFANT ASYLUM.

THIS inflammation has increased in frequency and severity during the latter half of the nineteenth century. Changes in the frequency or type of a disease are not infrequent during cycles in its history, without any appreciable cause, but as regards the malady under consideration, its increased frequency and severity are plainly due in great measure to diphtheria and influenza, from which our ancestors suffered but little.

Acute nasopharyngeal inflammation occurs in several distinct diseases, but with such similarity that we feel justified in considering it as one disease. Rhinologists and throat specialists treat of this malady at length, both in its acute and chronic forms, but their kinds of apparatus are too cumbersome for family use, and the patients with the acute form of inflammation are, many of them, too sick to leave their beds. I shall endeavor to point out the treatment which I have found most useful in nursery cases.

Etiology.—We are able to designate several causes of nasopharyngeal inflammation. It is a common experience that sudden exposure to wet and cold when the body is scantily clad, especially if it be perspiring and overheated is followed by nasopharyngeal catarrh. "Taking cold" signifies in most instances that the person, with or without a chilly sensation, has a nasopharyngeal catarrh, characterized by a thin mucous, and afterward, perhaps, by a mucopurulent discharge from the nostrils and throat. If the opinion as regards the cause be correct, and no other inflammations, as tonsillitis, laryngitis, or bronchitis, supervene, the patient soon recovers Obviously this malady is non-microbic.

Chemical or finely divided mechanical irritants inhaled in each inspiratory act also produce nasopharyngeal catarrh. Such irritants are obviously more abundant in a large city, with its many business transactions, than in the purer air of the country. If a sunbeam be allowed to enter a darkened room, numerous floating motes will be seen in it; and if on a cloudless and quiet day an observer stand at a distance from the city limits, he will see a dense mist or cloud resting over the entire city, and no doubt composed largely of such particles as float in the sunbeam. D. F. Lincoln, M.D., in his paper on the atmosphere, in Volume xviii of Ziemssen's Cyclopedia, page 636, says: "African organisms have been found in the air of Berlin. . . The animal and vegetable kingdoms furnish a great variety of material for dust . . . Bacteria, vibriones, and monads are found very frequently . . also fragments of insects are found." Probably an equally thorough examination would disclose similar impurities in the atmosphere of American cities. Motes floating in the air may convey fragmentary animal, as well as vegetable forms, and minuter objects seen only by the microscope, as the pollen of flowers, which is the admitted cause of catarrhus æstivus, or hay-fever, may be similarly conveyed. These substances inhaled necessarily produce more or less irritation and sensitiveness, and, in some instances, catarrh of the upper air-passages.

At the present time, probably the most common cause of nasopharyngeal catarrh in this country is the influenza, which produces multiform symptoms and lesions in the different organs, but according to my observations the primary lesion of influenza, in a large proportion of cases, is the catarrh of which we are treating, so that if two or more have this catarrh simultaneously in a family, and we are able to exclude measles and pertussis, the disease is probably influenza.

Influenza is not a new malady; our ancestors mentioned it. Sir Henry Holland wrote of it sixty years ago; but as scarlet fever was regarded as a mild, even trivial, malady in the time of Sydenham, so the influenza may have attacked our ancestors more mildly and for a shorter time than it has in Europe and America in the last six or seven years.

The smallness and portability, by currents of air, of the influenza bacillus enables it to enter the system readily by the usual modes of infection. Gaining entrance into and circulating in the blood, it is enabled to reach most of the organs, and there is probably no organ which has not experienced its irritating effect. Delafield and Prudden say: "There may be conjunctivitis, otitis, naso-

pharyngeal catarrh, tonsillitis, laryngitis, bronchitis, pneumonitis, pleuritis, gastritis, enteritis, or peripheral neuritis." A recent writer in a London medical journal enumerates as many more local maladies which result from influenza, and adds: "Mental incapacity remains long, and many patients affected in middle life speak of inability for bodily and mental work that was easy previously."

Observations have accumulated sufficiently to show that the minute bacilli of influenza have the power to penetrate the accessory tubes, sinuses, and deflections pertaining to the nasopharyngeal tract to a greater extent, probably, than any other pathogenic germ. They sometimes lodge upon the turbinated bones, enter the antrum of Highmore, Eustachian tubes, the middle ear, mastoid cells, the sphenoid and ethmoid sinuses, and, in those old enough, the frontal sinuses, producing unusual inflammations, with much suffering.

Cases might be related in confirmation of this statement. Thus, a man of good constitution and habits, attended by me, had such severe pain low in his forehead that he walked hurriedly, half-dressed, from one side of the room to the other, compressing with both hands the seat of the pain and moaning at each step. When the pain began to abate, he noticed distinctly a rubbing sensation when one of his eyes was moved in its socket —a sensation like that produced by rubbing the finger over a dry pane of glass. The inference was that the specific inflammation had extended to the frontal sinuses, and from them through the thin layer of bone to the orbit.

I shall relate one other case, reported in the London *Lancet*, October 19, 1895, showing how severely the accessory sinuses and cavities of the nasopharyngeal tract suffer from inflammation produced by the influenza bacillus, which apparently, in this case, entered the system through the nares and produced a severe, painful, and protracted inflammation of the antrum of Highmore. The patient, an adult, had constant pain in the left temporal, mastoid, and occipital regions since an attack of influenza, seven years previously. There was also a purulent discharge from the left nostril. On rhinoscopic examination, the anterior part of the left turbinated bone was found to be covered with small sessile vascular polypi, and the oozing of offensive pus from the middle meatus was constant. The amount of pus varied, and at night it ran down the throat. The carious teeth were extracted, and two holes were drilled into the antrum. A pyogenic membrane, forming a very complete cast of the central cavity, was removed, along with pus and caseous matter, through the opening in the antrum. Polypi were removed and their bases cauterized. Patient was soon well.

These cases show the tendency of nasopharyngeal catarrh to extend into collateral tubes and sinuses, producing severe and dangerous inflammatory lesions, unless promptly relieved by treatment. Pathological researches are so far advanced that we can now assert that the following diseases, which are attended by nasopharyngeal inflammation, have a microbic cause: Influenza, measles, pertussis, scarlet fever, diphtheria, pseudo-diphtheria, erysipelas, gonorrhea and syphilis.

It is a fact of clinical importance, as expressed by Delafield and Prudden, that "acute inflammation of the lymph-nodes usually occurs in connection with some inflammatory process in the region from which its lymph is gathered." The lymph gathered from the inflamed nasopharyngeal surface in an acute infectious disease, like scarlet fever or diphtheria, contains not only the specific microbes of the disease, but other microbes, notably the streptococcus and staphylococcus (Booker and others) and the toxins produced by them. These, conveyed in the lymph-current, are highly irritating, causing inflammation in the lymph-ducts and nodes (adenitis), and in the adjacent connective tissue (cellulitis). If the inflammation in an infectious disease be pharyngeal, and antiseptic treatment of the fauces be not used, a swelling usually forms along one or both sides of the neck, often of the size of a hen's egg, or larger, and if the skin becomes red upon the swelling, suppuration inevitably occurs. This common complication, which might be prevented by the early and frequent use of local disinfection, increases the emaciation and weakness and renders the prognosis more doubtful.

Symptoms.—The constitutional symptoms are mild or severe, according to the gravity of the inflammation and the nature of the primary disease, if one be present. If the nasopharyngitis be active and pretty general, fever, thirst, and anorexia occur. Frontal headache is common, from the proximity of the inflammation to the head or its extension to the frontal sinuses. Sneezing is the first symptom in many cases of coryza. As the inflamed membrane swells, more or less obstruction occurs to respiration. The breathing is noisy, especially during sleep, and in severe cases the patient is compelled to breathe through the mouth. If there be much obstruction to respiration, the suffering of the patient is considerable, from the sensation of fulness in the

nostrils, the headache, and the muscular effort required in each respiratory act.

In the commencement of coryza, the patient experiences a sensation of dryness in the nostrils, which is soon succeeded by a thin discharge of serous appearance. In the course of a few hours the secretion becomes mucopurulent and thicker. If the case becomes chronic, more or less persistent thickening of the mucous membrane and incrustations are likely to occur. One of the most dangerous of the acute and nasopharyngeal inflammations is that occurring in latent diphtheria. I allude to cases in which the visible part of the nostrils and fauces does not exhibit pseudo-membrane but a catarrhal inflammation, while a pseudo-membrane probably occupies the posterior nares, a location which is very favorable for disseminating diphtheria. In such cases early and local antiseptic treatment is very important.

Treatment.—I need not remind the reader that, even with microscopic examination, it is impossible in many cases to make a clear and positive diagnosis of the nature of an attack of nasopharyngeal inflammation until one or more days have elapsed, and yet there is no other disease that requires a more early diagnosis. Inasmuch as a large proportion of cases of nasopharyngeal inflammation have a microbic origin, antiseptic sprays or inhalations should ordinarily be used every hour or half-hour from the first visit. Other appropriate remedies should be prescribed subsequently, as the nature of the attack becomes apparent. Young infants having this malady often necessarily respire through the mouth, on account of the mucopurulent secretion, thickening infiltration and incrustations of the Schneiderian surface. This impediment to normal breathing through the nostrils obviously compels respiration through the mouth, so the amount of food taken is diminished. Loss of flesh and strength inevitably result in young infants who take their food by suction, unless the nasal inflammation be soon relieved.

It is evident from the nature of nasopharyngeal inflammation that, though its causes vary, non-irritating antiseptic and germicidal applications should, as we have said above, be used from the first, and at short intervals, with an appropriate atomizer, small nasal syringe, small cotton swab, camel's-hair pencil, or other convenient instrument. Even when the cause is exposure to cold, the inhaled air is often so full of microbes that antiseptic applications are indicated.

The temperature of the room should be maintained at about 73° and the air be moist. I have employed with apparent benefit the following mixture for supplying moist air to the nursery when nasopharyngeal disease is present:

℞ Ol. Eucalypti, Acidi Carbolici aa . . . . ℥ i
Terebinthinæ . . . . ℥ viii
Misce.

In hot weather, two towels of ordinary size, wrung out of hot water, should be spread at length on a table, with one or two newspapers underneath, and two tablespoonfuls of the above mixture sprinkled over them. This should be repeated every fourth hour. If the weather be cold, the two tablespoonfuls may be added to two quarts of water in a tin, zinc, or other vessel having a broad surface, and maintained at a temperature of 170° to 190° F., which causes simmering, but not boiling. This disinfects the air that is respired and, at the same time, renders it moist. This treatment may be properly continued during the active period of the inflammation.

Common mild attacks of coryza require simple treatment. The bowels should be kept open and the body comfortably clothed. Inunction of the nostrils with carbolized vaselin is a popular remedy, and it seems to give some relief. A five per cent. solution of common salt in warm water, injected into the nostrils with a small syringe, aids materially in removing the muco-pus, which obstructs the respiration.

The following formulæ are also useful in the treatment of naso-faucial inflammations:

℞ Acidi Boraci . . . . . ℥ i
Sodii Biborat . . . . . ℥ ii
Aquæ . . . . . ℥ viii
Misce.

℞ Sodii Chloridi . . . . . ℥ i
Sodii Biborat . . . . . ℥ ii
Aquæ . . . . . Oi
Misce.

Either mixture should be used hourly, or at longer intervals, as a spray for the nostrils and fauces. But while other sprays are useful, the following formula will be found eminently satisfactory for the purposes for which sprays are employed. I have recommended it for many patients, and to physicians, who have, so far as I recollect, uniformly reported favorably.

℞ Creosoti Morson's Beechwood . gtt. ii-iii
Seiler's Tablets (alkaline and antiseptic) i-ii
Aquæ Distillat . . . . ℥ iii
Misce.

With a simple hand atomizer spray nostrils and throat every hour to two or three hours, compressing the bulb from four to six times, and inhaling deeply the inspired vapor.

The following is a similar formula, and might in some instances be substituted for Seiler's solution:

℞ Creosoti Morson's Beechwood . gtt. ii–iii
Dobell's Solution . . . ʒi
Aquæ Puræ . . . . ʒiii
Misce.

Of course the measures for local use which we have recommended, can be safely employed by families before or between the physician's visits. All are aware, as we have stated elsewhere, that internal treatment also may be required, according to the nature of the nasopharyngeal catarrh and the exigencies which may arise.

SYDENHAM'S CHOREA; AN ANALYTICAL STUDY OF 125 CASES.

By WILLIAM BROADDUS PRITCHARD, M.D.,
OF NEW YORK;
ADJUNCT PROFESSOR OF MENTAL AND NERVOUS DISEASES, NEW YORK POLYCLINIC.

CHOREA is a very old and familiar affection. It has been recognized as an entity almost since the days of prehistoric medicine. It has attracted the attention, as a field for study, of many medical men eminently qualified in clinical and pathological research, and yet there are several unsettled problems which remain to confuse our conception of the pathogenesis, and render uncertain the results from treatment. Our knowledge of the pathology involved is most indefinite and unsatisfactory. No two autopsies reflect the same findings, although minute punctiform hemorrhages, or minute emboli of the cortical vessels, with more or less congestion, have been noted with suggestive frequency by different observers. A theory of microbic origin has also its adherents, though facts are few. The etiology and pathogenesis will be easily deducible, reasoning from effect to cause; when once the pathology is established, and a more rational basis of treatment will also be attained as a correlated result. Clinical facts often indicate or suggest a line of pathological investigation, sometimes with happy results. Analytical studies of a series of cases, made with this object, are, therefore, often of much value.

During the years 1893–95, I saw in private practice and at my clinic at the New York Polyclinic, 125 cases of simple or Sydenham's chorea. In nearly all of these cases full record was made of the facts, as far as could be determined, of heredity, age at onset of first attack, exciting cause, month of onset both as to primary and relapsing attacks, number of relapses, distribution of movements, mental condition, presence or absence of personal rheumatism or heart disease, and various special symptomatic conditions noted in individual cases. Of these 125 patients, 45 were males, 80 were females. The average age at the time of observation was 9¾ years, the youngest patient aged two years, the oldest (relapsing case), twenty-eight years old. Including parental phthisis, about one-fourth showed distinct lineal neurotic heredity as follows: Epilepsy 3, chorea 15, migraine 5, phthisis 5, insanity 1, total, 29. One patient, a girl, aged eight years, presented a history illustrating the most intense neurotic saturation in a family I have ever noted. Her father suffered from migraine, the mother was an epileptic, dying from an accident, a sister had chorea, a brother some form of paralysis, which I concluded from the description to have been poliomyelitis, and a maternal aunt died insane.

The exciting cause could not be determined in the majority of instances, but the number of cases in which the first symptoms of chorea quickly followed some one of the various infectious diseases of childhood, and particularly scarlet fever, was remarkable. Three followed grip, 1 the mumps, 5 measles, and 20 scarlet fever. In 4 cases there was a clear history of trauma involving injury to the head or concussion. Fright, or anger, or other emotional disturbance, was ascribed as the cause in 17 cases, and in one of my private patients, a young girl of thirteen, the symptoms (first attack) developed abruptly while in the theater, from the sudden, complete, accidental darkness, which resulted from some defect in the lighting apparatus. Her attack lasted seven weeks and was quite severe, the child having to be fed by an attendant for a time on account of the excessive violence of the ataxic movements. In 7 cases the disease manifested itself at the period of puberty, and no other cause was assignable, but it is to be noted that in three of these cases there was a neurotic heredity. Thirty cases began in the spring months (March 7, April 8, May 10, spring 5); 30 in the summer (June 8, July 10, August 4, summer 8); 5 in the fall (September 2, October 1, November 1, fall 1); and 12 during the winter months (December 3, January 3, February 6). In the remaining 48 cases the month or season could not be positively determined.

The distribution of the choreic movements was carefully noted in 101 cases, being limited to the left side in 19, to the right in 18, and involving both sides, with but slight differences in degree, in 64. As a rule, only one side was affected in patients with primary attacks, while the more frequent the relapses the greater the tendency to

general involvement. The speech and movements of the tongue were affected in 14 patients. The coexistence of heart disease and a history of rheumatism were points of special inquiry. In many instances suspected cardiac lesions were submitted to Professor Page of the department of diseases of the heart and lungs, for opinion. In no case was a history of vague limb, or muscle, or joint, or "growing" pains, accepted as rheumatic, only the frank, explosive manifestations of this disease being considered. Nine patients gave histories of well-defined attacks of rheumatism, and in one patient, a girl aged eight years, there was a history of three such attacks, chorea being present concurrently in one of them. Of those with well-marked evidences of cardiac disturbance, 11 presented conditions of organic disease, 3 of these cases of aortic regurgitation. In 8 cases there was more or less marked disturbance of the heart's function and rhythm, but no positively demonstrable lesion. All of these 8 cases exhibited a pulse-rate above the normal. The mental condition was noted in all cases, and in 75 no variation from the normal average in intelligence and psychical equilibrium for age was apparent. In 34 cases the mental state was far above the average, these children being of the precocious type, excelling in their studies and in some instances evidencing a high order of psychical activity and development. Only 7 were noted as "dull," and only 4 as exhibiting mental states which would justify the application of the term demented, and even here, in 2 cases, the term was open to criticism in its strictly technical significance. Other mental perversions noted were extreme irritability in 3, hysteria in 1, and rather intense melancholy depression in 1, a girl of fourteen. Most of these cases presenting variations from the normal, in the mental state were patients in whom one or more relapses had occurred.

Of the entire number of cases, 125 in all, there was a history of at least two attacks in 54, three attacks in 17, and four or more in 6 patients. Among the anomalous or unusual symptoms noted was optic atrophy, distinctly present in one case, and a mild optic neuritis in another. Insufficiency of the eye muscles, esophoria, astigmatism, and other minor anomalies of the visual apparatus were noted in several cases. Strabismus was present in decided form in 4 patients. A history of eneuresis was volunteered in 4 cases and was probably present in others, but not noted, as no special inquiry was made with regard to it. Anemia, more or less profound in degree, was exceedingly common. Paralysis of the extremities was not observed in a single case, even in minor degree, although several patients, through anemic exhaustion, or the extreme ataxic jerkings of the limbs, were rendered helpless. Atrophy of the muscles, observed in three cases by Rondot,[1] I have never seen present in Sydenham's chorea.

A recapitulation and comparison with the observations of others may not be without interest and value. As regards sex, I found the proportion to be about two females to one male (45 males, 80 females). All statistics show a peculiar susceptibility in females as compared with males. Wharton and Vickery,[2] in a study of 76 cases, found the ratio to be 2 males to 3 females. They quote Broadbent, however, as finding the ratio to be 2 females to 1 male, and Gowers and Goodall give the proportion as 5 to 2. Koch,[3] in a total of 267 cases, found 100 males to 167 females. In my series of 125 cases I found a distinct neurotic lineal heredity in nearly twenty-five per cent., a fact of rather remarkable interest, in view of Koch's statement that heredity is not significant. Koch's observations, with reference to the etiological relationship of the seasons, are no less peculiar and at variance with nearly all other observers. He finds the disease most prevalent in winter, and states that twenty-two per cent. of his cases occurred in December. Morris J. Lewis,[4] who made a special study of the effects of climatic conditions and the influence of the seasons in the development of chorea, found in an analysis of 1383 cases, that the disease developed in the spring in 491, summer 382, autumn 204, and winter 306. My own observations are fairly in accord with these figures, and are further supported by Dana,[5] who found the largest number of cases occurring during the spring months.

The relationship of chorea and rheumatism, and of chorea and heart disease, is a subject of much importance in its bearings upon pathogenesis and treatment. While the exact relationship is still a matter of some doubt, there can be no question but that a certain etiological kinship does exist between the three, although chorea may unquestionably occur without any antecedent or personal rheumatism or cardiac disease. Sir Dyce Duckworth apparently believed to the contrary, for he is quoted by Sturgis[6] as teaching that rheumatism holds first place in the etiology of chorea, the latter being simply a manifestation of the rheumatic habit. Sturgis himself reports a rheu-

matic element in twenty-five per cent. of the 100 cases analyzed by him. Dujardin Beaumetz[1] recognizes only two etiological factors in chorea, rheumatism and hysteria. (In only one of my cases was there any hysterical element. Racial peculiarities might, perhaps, partially explain this marked discrepancy, but it is too great to be accounted for solely on this ground.) Koch, in the series referred to, found a history of rheumatism in eighteen per cent., and of valvular heart disease in fourteen per cent. Walton and Vickery found in 36 cases no possible rheumatic or cardiac element of disease, but in the total of 76 cases, organic heart disease was found to the extent of 27.63 per cent., and rheumatism 23.68 per cent. Dana found a history of parental rheumatism in eight per cent., and of personal rheumatism in five per cent. in 130 cases. My own observations are more nearly in accord with Dana's figures, as I found a clear history of personal rheumatism in only about seven per cent., while, including both the organic and functional cases, I found decided disturbance of the heart's action in 19 cases, or about fifteen per cent.

The following conclusions seem legitimate:

1. Chorea is more common in females, in the proportion of two to one, than in males.

2. The disease is more prevalent in the spring months than at any other season of the year.

3. A neurotic heredity is of unquestionable importance as an etiological factor.

4. The disease seems to be especially liable to development in the unusually intelligent and precocious. Mental deterioration or perversion occurs only as a result (as a rule) of relapses of the disease.

5. Chorea may occur independently of either heart disease or rheumatism, but the frequency with which the three are found to be present in association is more than a coincidence. Further study is necessary before any positive conclusion can be reached as to the exact significance of this relationship.

SYSTEMIC INFECTION FROM GONORRHEA, WITH THE REPORT OF A FATAL CASE.

BY J. M. ROBINSON, M.D.,
OF DULUTH, MINN.

CONSIDERABLE evidence is gradually accumulating concerning the liability to general constitutional infection from gonorrhea. So long ago as 1860, Barwell[2] enunciated the view that so-called gonorrheal rheumatism was a form or manifestation of pyemia, and this idea has continually gained credence. For a long time, however, arthritis was the only extragenital complication of gonorrhea which appears to have received attention. Finally it was observed that iritis and capsulitis occasionally accompanied the arthritic complication, and then it was suspected that any of the serous membranes might become inflamed through the agency of the absorbed toxic products of a specific urethritis.

In 1876 a French writer, Marty,[1] after reviewing several cases of gonorrheal synovitis, which were accompanied by inflammation of other serous membranes, concluded that "Gonorrhea may be complicated with inflammation of all of the serous membranes, and may act in a direct way on each of them. Rheumatism is by no means a necessary middle condition between the specific lesion and the lesion of the serous membrane, although the coexistence of the two complications is most frequent."

The term "rheumatism" in this connection is unfortunate and misleading, for the process is essentially a septic one. During an attack of specific urethritis, gonococci or other pyogenic germs associated with them or their ptomains may enter the circulation. Then by far the most common clinical manifestation of such an occurrence is an inflammation of the serous lining of one or more of the larger joints. But recent clinical and bacteriological evidence has shown that Marty was quite correct in assuming that other serous membranes might be attacked by the circulating poisons. On more rare occasions it seems probable that gonorrhea may give rise to a general septicemia, although some secondary local lesion will usually be found to predominate at the autopsy, if the case terminate fatally.

Gluzinski of Vienna[2] collected thirty-one cases of acute peri- and endocarditis which supervened in the course of gonorrhea. Not all of these were accompanied by an involvement of the joints, and some assumed the character of an acute infectious disease—as ulcerative endocarditis.

McDonnell[3] collected from the case-books of the Montreal General Hospital twenty-seven cases of gonorrheal arthritis, of which six were said to have shown signs of cardiac disease.

See[4] mentions two cases of gonorrheal pleurisy.

Dr. Panus[5] has reported an instance in which gonorrhea was followed by fever, intense headache, and ocular symptoms, which ended in optic

atrophy. He ascribed the trouble to meningitis of gonorrheal origin.

Leyden[1] has reported a fatal case of meningomyelitis, which apparently originated from an extensive gonorrheal cystitis.

The assumption that such cases might be merely coincidental has been set aside by the discovery of gonococci at the seat of the secondary lesion. In the *American Journal of Medical Science*, July, 1895, is an abstract of a paper recounting a case of specific epididymitis, which was followed by arthritis and fatal ulcerative endocarditis. Microscopic examination of fragments of the cardiac valves disclosed gonococci. Two similar cases have been noted in the MEDICAL NEWS.[2]

Many instances have been reported where the specific cocci have been found in the pus of complicating arthritis.[3] And, finally gonococci have been found in the blood of patients suffering from involvement of the joints.[4] It is very probable that the infection is usually of a mixed character.

In the text-books on genito-urinary diseases which I have at hand, such as Keyes, Bumstead and Taylor, and Durkee, little or no reference is made to the possibility of a general infection following gonorrhea. But the finding of the specific germs in various parts of the body suggests that such a result may occasionally be expected; and the very fact of the occurrence and frequency of gonorrheal bubo tends to show how often the poisons of "clap" start out to invade the system, and are only prevented from so doing, in the ordinary case, by the angry intervention of the inguinal glands. Often it is observed that specific urethritis is attended by a mild fever, which is undoubtedly due to a slight septicemia. Very recently I have had an instance of this kind in my own practice. A young man began to complain of headache and chills on the third day of the urethral discharge. His temperature, when first taken was 103°, and after this a mild pyrexia continued for nine days. The patient's family assumed that he had typhoid fever, an idea which, in deference to the wishes of the sufferer, I did not attempt to dispel, although there appeared no symptoms which could be attributed to any other origin than the inflamed urethra. There were also no signs of arthritis, pericarditis, or other complication.

I take it that such a condition as this might better bear the title of "gonorrheal fever," since it was distinctly a septic affair, than to lurk under the name of "urethral fever," which still carries with it the vague idea of some obscure nervous influence.

If a thermometer be regularly employed when patients suffering from the first effects of specific urethritis present themselves for examination, it will usually be found that there is a slight elevation of temperature. This may not be more than 100°, but it serves to indicate a slight tendency toward septic absorption. At the same time, there will occasionally be heard the complaint of headache and a feeling of malaise. Such symptoms pass rapidly away; it is in the later stages of the disease that an elevation of temperature is of more consequence, when it usually precedes or attends the various local complications of an inflammatory character. It is at this time, too, that the distant serous membranes are most likely to be attacked.

Without having an opportunity to make an extensive examination of the literature on the subject, I have noted the reports of six fatal cases of gonorrheal origin—three from arthritis and endocarditis, and one from meningitis have been herein mentioned. Another death from gonorrheal endocarditis has been reported by DeFleury,[1] and recently, in the MEDICAL NEWS, Dr. Hawkins[2] has detailed a fatal case of gonorrheal rheumatism. It was unfortunate in this instance that the diagnosis was not confirmed by an autopsy, nor does it appear that a bacteriological examination completed the case.[3]

To this brief list I shall now add the following:

A. C., aged thirty-two, employed as a hotel clerk, was taken suddenly ill in the evening after attending to his usual work during the day. When I called to see the patient, on the following morning, the proprietor of the place told me that the man was a stranger in the city and had worked for him about six weeks, during which time he had attended strictly to business and had appeared to be in good health.

On first appearance, the case seemed like the onset of some acute infectious disease. The patient stated that on the previous day he had suffered slightly from headache, which increased toward evening. About midnight he had a severe chill, which was several times repeated. He had vomited freely, and complained of intense headache and "pain all over." His temperature was 105°; pulse 120; face deeply flushed, and conjunctivæ injected.

Inquiries regarding his family and personal history gave negative results. He had had the

[3] Reference is chiefly made in this article to gonorrhea in the male subject. Severe cases of gonorrheal salpingitis, peritonitis, etc., are, of course, more common.

usual diseases of childhood; denied syphilis; acknowledged occasional alcoholic excesses; had never suffered from rheumatism in any form, and had recently been subjected to no unusual exposure or fatigue. His general physique was excellent; his weight about 170 pounds. A specimen of urine obtained at this time was normal in specific gravity and color, but contained a slight trace of albumin and a few pus-cells; the urethra had probably been washed by a more copious urination shortly before this was obtained.

During the first day of his illness, he developed a low type of delirium, from which he could, however, be easily aroused. When left alone he talked excitedly to himself, and was very restless, but made no attempt to leave his bed. This mental condition continued until coma supervened a few hours before his death, which occurred within four days of the time when he was first taken ill.

At times he complained of severe pain, but had difficulty in locating it; there seemed to exist a condition of general hyperesthesia, and he complained of soreness in various parts of the body. Pressure over the toes, ankle, and knee-joints elicited pain, but only on the last day of his illness was swelling detected. For the most part of the time he moved himself without difficulty, and in the earlier part of his attack there was no indication that the joints were especially involved. The temperature was irregular, varying from 99 to 105°; sweating was not marked; there were no pulmonary signs. The pupils remained contracted throughout; the expression was anxious rather than drowsy. Tongue red and glazed. The vomited matter, which at first was made up of bile-stained fluid, later consisted of mucus flecked with blood. There were no abdominal symptoms; the bowels were moved by calomel and an enema. By the third day, the entire body was dotted with purpuric spots, and it became evident that the patient was suffering from intense blood-poisoning, although no source of infection could be detected. The pulse was rapid and of high tension; for the first three days, the heart-sounds were clear and distinct, but on the fourth day became muffled; there were no murmurs.

After the purpuric eruption appeared, the patient grew rapidly weaker, and the delirium and jactitation were followed by coma and evidences of general nervous exhaustion.

Several diagnoses were suggested but none of them seemed quite satisfactory. The occurrence of intense headache and contracted pupils, with vomiting and general hyperesthesia, favored cerebrospinal fever. Since purpura and joint symptoms occasionally occur in this disease, such a view of the case seemed plausible. The severe onset and protean character determined against acute articular rheumatism; the involvement of the joints seemed to be secondary; there was besides no sweating, nor did the one specimen of urine obtained, reveal an excess of urates or uric acid. And finally, the attack had assumed a resemblance to the few reported cases of acute purpura hemorrhagica. The blood in the vomited mucus showed that small hemorrhages had taken place in the gastric mucous membrane. Since no definite diagnosis could be arrived at, the case was treated as one of malignant septicemia; the autopsy showed that this conclusion was well founded, and the most probable origin of the blood sepsis was revealed. The following are the notes taken at the *post-mortem* table, condensed:

Body of man about thirty years old; height five feet ten inches; weight about 165 pounds. *Rigor mortis* in extremities (thirty hours after death). Purpuric spots scattered over entire body; left knee-joint seems to be slightly swollen; inguinal lymphatics can be felt slightly enlarged. On incision, the blood is found to be dark and fluid. No hemorrhages can be discovered in the muscular or areolar tissue. Pleuræ normal. Hypostatic congestion of both lungs. Pericardial fluid a little cloudy; quantity about two ounces; on the visceral layers of the pericardium is a white patch about the size of a dime; along the left coronary artery are a dozen punctate hemorrhages; there are no other signs of pericarditis. Cardiac muscle flabby and somewhat grayish; "chicken fat" clots; valves normal; two minute hemorrhages are found in the aortic lining, an inch from the valve. Stomach empty; vessels of mucous membrane deeply congested, and ecchymomata cover the posterior surface, but no free blood is found in the stomach or intestines, the latter appear to be in normal condition. Mesenteric glands slightly enlarged. Pancreas and liver normal. Spleen much enlarged, soft, and friable. On the capsule of the left kidney is a small blood clot, but otherwise these organs are normal in appearance. Ureters and bladder normal.

The cerebral and spinal meninges are deeply congested, but there are no inflammatory changes. No purulent foci found in any of the viscera. The synovial membranes of both knee-joints are bathed in their pus, but the quantity is not sufficient to flow from the joints when opened. A similar condition is found in the metatarso-phalangeal joints of the great toes. A minute quantity of pus is also found in three out of six of the other toe-joints which are opened. The joints of the upper extremity are free from pus, but the synovial fluid of the elbows is cloudy.

After the death of the patient, among his effects was found a penis syringe, which showed signs of recent use, and also a broken package of absorbent cotton. Upon finding this clue, I opened the urethra and found behind a stricture of large caliber, in the middle of the spongy portion, a

drop or two of thin pus; from this point, evidences of inflammation were found as far back as the prostate gland. Cowper's glands were enlarged, and the duct of one was dilated and could be easily noted. The patient had been suffering from chronic posterior urethritis. Gonococci were present in the urethral pus. The body was, unfortunately, removed before I had an opportunity to return for a specimen of the pus in the joints, but I am quite well satisfied that the urethra was the original source of the infection. Had the pyarthrosis been primary symptoms referable to the joints, would have manifested themselves earlier. Certain it is, that a complete *post-mortem* examination in this case prevented the use of the word *idiopathic*, which has no proper place in the study of septic and pyemic diseases.

In concluding this report, I call to mind those lighthearted devotees of the bagnio, who scoff at a gonorrhea, and would as soon be so afflicted as suffer with a "cold," but then a man may "catch *his death* o' cold," and so too, as I have here shown, may he die of the "clap."

CLINICAL LECTURE.

SPINAL PARALYSIS.[1]

By CHARLES CARY, M.D.,
OF BUFFALO, N. Y.;
PROFESSOR OF THERAPEUTICS, UNIVERSITY OF BUFFALO.

An Italian laborer, aged forty, was injured two months ago by a tree falling across the small of his back. The accident did not disable him immediately, but within a few hours, absolute paralysis of the lower extremities set in, accompanied with anesthesia and with loss of control over the bladder and bowels. Subsequently, the paralysis was succeeded by paresis, and the muscular sense was so far restored that deep manipulation became perceptible.

Upon entering the hospital a few days ago, the patient complained of pain in the lumbar region and, on examination, posterior curvature was found. On questioning the patient, we learned that the pain ran down his legs, and that sensation in the lower extremities was still somewhat impaired. He controlled the urine and feces, and could walk fairly well.

It is a very important point to determine whether the patient could walk immediately after the accident or not. In this particular, there is a decrepancy between the history and the present statement of the patient. He says that he lay on the ground for about an hour after the accident, and was then lifted into a wagon and taken out of the woods. There was no involuntary evacuation of the bladder or bowels at that time, but the absence of these symptoms is not significant, since there may have been no pressure to call for a passage. The man was carried in a wagon some miles to Springfield, where he arrived so cold and paralyzed that his friends at first thought he was dead. The truth or falsity of our understanding of the facts of the case will determine the correctness or incorrectness of our diagnosis.

The patient can now walk, as you see, and he crosses his legs and flexes them without trouble, though there may be some loss of power. He feels the prick of a pin in both legs, but he says it does not hurt, though I make quite a vigorous thrust. The same test applied to the arms elicits even less complaint of pain, so that we must admit that any apparent diminution of sensibility at present is peculiar to the individual. It not infrequently happens that men, accustomed to rough work and exposure, are incapable of appreciating as painful, slight injuries that would be intensely so to those of higher nervous organization. The patellar reflex is not quite so strong in the right leg as in the left, but there is no conspicious deviation from the normal. Although the patient walks fairly well so far as mere ability to move is concerned, his gait is a little staggering and heavy, and he complains that the effort causes pain in the small of his back and running down the right leg. It hurts him when I press down on his shoulders. This fact should at once lead to the investigation of the condition of the spine, to determine if there is any yielding of the bony support that allows the pressure to be communicated to the cord. There is nothing very striking about the appearance of the spine, but there is a prominence of the lower dorsal and the upper one or two lumbar vertebral spinous processes. Pressure against the spine straightens the deformity somewhat, but it does not wholly disappear. The pain on downward pressure is located at this protuberance.

With a history as vague and contradictory as this, we can do little more than analyze the symptoms and statements of the patient and get at an approximate diagnosis. In the first place, we may be certain that the man received a severe injury in the region of the lower dorsal and upper lumbar vertebræ. As a result of the blow, the man was soon, though apparently not immediately, paralyzed. This paralysis may have been due to shock, for, in many spine and head injuries, the spinal or cerebral center is stunned so that a marked paralysis results, but disappears so soon that we may be sure that no absolute lesion of the centers was sustained. I have known such cases in which, merely as the result of shock, there was such profound paralysis that urine and feces were discharged at once. Shock of this sort, however—that is concussion—does not last long, while concussion of the cord is of much shorter duration than concussion of the brain. These cases of concussion of the cord have attained considerable notoriety as the results of railroad accidents. Serious chronic spinal lesions are often alleged to follow railroad injury, but these cases are mainly hoaxes, and recovery ensues soon after the obtaining of a verdict. I have no doubt, however, that shock of the spinal cord can and does occur.

The ride in the wagon would be sufficient to aggravate the symptoms of paralysis and shock. I do not question that the patient really was paralyzed, for he says that the lower part of his body and his legs seemed to be dead. What was probably the nature of the lesion? Strike

[1] Clinic at Buffalo General Hospital.

where you will, a blow to the living body, if it be sufficiently severe, is followed by the pouring out of serum, which becomes mixed with blood-cells if the injury is sufficient to rupture some minute vessel, and this may amount to an actual hemorrhage if the violence is great. The outpouring is not necessarily in the exact location of the blow upon the skin, but it must be in the line of violence to the tissues. In the present case, we have to think of an exudate occurring somewhere in the neighborhood of the spinal cord. So far as the paralytic symptoms are concerned, we may ignore the injury done to the bony parts and the ligaments outside the spinal canal. All such injuries would be diagnosed and treated on the general principles of surgical practice, but, except for concomitant shock, they would not be attended by any nervous symptoms. It is not possible at this late date to determine exactly what injury was done to the outside structures, but it appears from the contour of the spinal column that there may have been a fracture of the vertebræ. A displacement of the bony arch about the spinal cord would suffice for the establishment of a paralysis, but it would be relieved by the reduction of the dislocation and, on the other hand, there would not be recovery unless the deformity was corrected. The history of this case is entirely contrary to any such hypothesis. The paralysis did not come on instantly as if it were caused by the displacement of bone, it was not suddenly relieved by any manipulation, the recovery of function has not depended upon the reduction of fractured and displaced bone, but has progressed gradually. Moreover, the deformity persists, so that if there were a fracture of a vertebra at the time of the accident, it was not directly connected with the paralysis. Coincident with whatever damage to the vertebræ may be assumed, there was the outpouring into the spinal canal of some exudate, whose gradual but quite rapid accumulation led to a paralysis, which rapidly deepened, but did not occur at the moment of injury. The intensity and duration of a paralysis beginning in this way, depends on the size and location of the blood-clot and the rapidity of its resorption. As to the question between blood and serum, a serous exudate would be quite rapidly absorbed, while a blood-clot would probably first go on to organization and then be gradually, and perhaps, incompletely, reabsorbed. I learn that the man has never been any better since the injury than he is at present, so that the history points quite positively to the existence of a blood-clot. The condition is improving, and that means that the blood-clot is diminishing so that the prognosis is fairly good. While a massive clot is scarcely ever completely absorbed, a mixed hemorrhagic and serous exudation would account for the symptoms of the case and for the improvement, and would allow the hope of perfect recovery, ultimately.

A point to be considered more carefully, is the deviation of the spine. Is it old or new? Is it progressive, from which we would anticipate more serious disease which might later make actual bony pressure on the cord, or is it on the wane? I should rather not express a positive opinion on these questions until the opportunity had been afforded to watch the case for some time. I believe, however, that, if there were an injury to the anterior portion of the spine, with serious lesion of the bodies of the vertebræ, the patient would throw his weight backward and rest his hands on his hips, so as to relieve the vertebræ of pressure as much as possible. On the other hand, if there were inflammation of the vertebral arches, he would walk, leaning forward so as to throw the weight of the body onto the sound anterior part of the vertebræ. As a matter of fact, the gait of the patient, though unsteady and assisted by the holding of the hands on the hips, is not characteristic of either form of vertebral disease. I think that the probability is in favor of the non-existence of serious disorganization of either arch or body, but of some little irritation posteriorly to the spinal canal. The evidence in favor of some displacement at the time of the accident, is confirmatory of this view of the case.

The treatment of the case deserves some attention. I think that if I had seen the man soon after the injury, I should have kept him flat on his back, so as to avoid all movement of the spine. After the first shock had subsided, I should have given him pretty active saline cathartics to deplete the system and reduce arterial tension, and thus tend to prevent the further outpouring of blood in the spinal canal. Later, there would have been an indication for the administration of iodids, in order to promote the absorption of whatever exudate had been thrown out. Extension of the spine to prevent deformity, if there really were fracture, would have been indicated and, at any rate, it would have served to keep the spine stationary. At first, the most appropriate method would have been by elevating the foot of the bed and applying counter-extension. I should still suggest potassium iodid to aid in the absorption of the exudate and, as long as pressure on the shoulders causes pain, I should advise that he be kept in bed. If the tenderness to pressure on the shoulders persisted after the time when the man should be walking about for the sake of necessary exercise, I should support the spine by means of a plaster jacket. I should, however, first test the usefulness of the jacket by extending the man in the perpendicular direction in order to learn if the projection of the spine was diminished. It is not uncommon to see men with such backs who have never met with any accident, and it may be that we are over-anxious about this man's spine. Even the skin over the projection is somewhat callous, and it may be that he has simply become bent from hard labor. The case, however, demands great care, and it is better to waste our time in watching a condition which has preceded the injury than to allow a recent deformity to become aggravated, for the development of a positive curvature of the spinal column would tend to increase the man's paresis, and would be very serious. I have nothing further to say regarding treatment, except that the diet should be liberal, and that various symptoms may arise requiring attention, which cannot be anticipated in detail.

A Charter Revoked.—The Illinois courts have received such evidences of fraud in the management of the Illinois Health University, located at Chicago, that they have decided to revoke its charter.

CLINICAL MEMORANDA.

REPORT OF A CASE OF IMPERFECT CLOSURE OF THE AURICULAR AND VENTRICULAR SEPTA, IN A MAN DEAD AT THE AGE OF FIFTY YEARS FROM ABSCESS OF THE BRAIN.[1]

BY FREDERICK A. PACKARD, M.D.,
OF PHILADELPHIA.

THE patient from whom this specimen was removed was admitted to the Episcopal Hospital on July 6, 1893.

He was an American, a sailor by occupation, and was engaged in his ordinary work at the onset of his last illness. His family history contains nothing of interest. He was always healthy, his only illness having been an attack of measles. He denied syphilitic infection, but has had gonorrhea. He remembers no injury to his head.

His last illness began suddenly, ten days before admission to the Hospital. He suddenly partially lost consciousness, and remained in a semi-conscious condition for about ten minutes. His friends told him later that while in this condition he had localized convulsion, involving the muscles of the right eye, the right side of the face, right side of neck, back, and chest, the right arm, and to a less extent of the right leg. He said that after regaining consciousness he had a numb feeling in the whole right side of the body. He was, however, able to walk, to raise the right arm, and to talk without difficulty. Four days later, he had another attack of the same character, in which he was totally unconscious. After this attack the right side felt very weak, though he thinks sensation was perfectly preserved. The arm and leg continued useful.

His condition on admission may be summarized as follows: He was a powerfully built, well-nourished man. Face bronzed, but more dusky than would be the case from exposure to the sun alone. Gums darker than normal. Lips very dark and apparently congested. Pupils equal and normal; no ptosis or other sign of interference with muscles of eye or lids. Face symmetrical. Tongue coated, but protruded in median line. Right arm and leg can be moved, but are distinctly feeble. Can talk and swallow perfectly. No lesion of ears. Examination of the heart showed slight enlargement (direction of enlargement not stated in the copy of the notes in my possession) and a blowing systolic murmur, most plainly heard at the apex, but also present distinctly over the body of the heart. The lungs were negative, save for the presence of a few subcrepitant râles on both sides posteriorly. Examination of the abdomen was negative. All of the tendon reflexes were found to be normal, save for slight increase of the knee-jerk and the presence of ankle-clonus on the right side. The temperature was normal, the pulse 80, respirations 24. Urine normal. The late Dr. Heyl, at that time ophthalmologist to the Hospital, kindly examined the eyes for me and reported: O. D., inner margin of disk obscured; tortuosity of retinal vessels; O. S., vessels tortuous; disk normal. There was no glandular enlargement, the teeth were normal, and there were no skin lesions, save for a few blotchy areas on the upper third of the legs.

He was put to bed, an ice-cap was applied to the head, and he was given a five-grain dose of calomel, which was to be followed by the iodid of potash, in doses of ten grains, three times daily.

Nothing new developed until the night of July 8th. He then had a slight local convulsion, but the note of the next day says that "It did not bother him sufficiently to call the attention of the nurse to it." On the next day the patient seemed no worse.

At 6.15 A.M. on July 10th the patient commenced to be convulsed again. The right arm and leg began to jerk violently and rhythmically at intervals of two or three seconds. The alternate contraction and relaxation of the muscles closely resembled the effect produced by the slowly interrupted faradic current. The whole right side of the face and body was concerned in the convulsion, the muscles most involved being those of the right upper eyelid, the right side of the face, right side of neck, chest, and back, and the right arm. The right leg only occasionally contracted spasmodically. The note is not very clear as to the mental condition during the attack, but states that "there was no pain whatever," seeming, therefore, to corroborate my memory in regard to the more or less perfect retention of consciousness during the seizure. The attack lasted three-quarters of an hour. After the attack was past he complained of feeling tired, and it was noted that the right arm and leg were distinctly weaker. Careful examination showed no change in sensation.

On the next day (July 11th) he had no attack, but complained of a vague sensation in the left side of the head, that made him apprehensive of a seizure. This sensation was lessened by the application of an ice-bag.

On July 12th the patient was more stuporous, and was unable to raise the right arm, to articulate distinctly, or to put out his tongue. His temperature, which for the two preceding days ranged from 98.2 to 99.4°, rose, by 2 P.M., to 100°. A small quantity of urine was obtained by catheter, and found to be highly albuminous. He was put on the protoiodid of mercury on this day.

On the morning of July 13th the temperature was 99.4°, pulse 84, respirations 20. He was unable to move the right arm, and could not talk. Swallowing was quite a difficult act. Careful examination showed no other change in his condition. In the afternoon the temperature rose to 102.4° and his respirations became more labored.

On July 14th the morning temperature was 99°, pulse 90, respirations 22. He had a large number of involuntary stools since the day before. He was unable to take nourishment by the mouth, and was given nutrient enemata. Mercurial inunctions were instituted and the nape was well cupped. During the day Cheyne-Stokes breathing developed. In the evening the temperature rose to 102.6°, pulse 104, respirations 26.

During the night and the next day the patient remained unconscious, but no convulsions were present (nor had he had any since July 10th). Death occurred at 5 P.M.

The diagnosis made before death was tumor of the brain of latent course, with sudden accession of symptoms due

[1] Read before the College of Physicians of Philadelphia, May 6, 1896.

to hemorrhage within its substance. The location of the tumor was supposed to be in the subcortical region on the left side of the brain, the destruction of brain-tissue being probably greatest near the origin of the internal capsule, but it was supposed that the hemorrhage was at first most marked near the cortical side of the tumor, producing irritation of the cortex and convulsive seizures. How erroneous the diagnosis was can be seen by the report of the necropsy. While the possibility of cerebral abscess was, of course, considered, the absence of middle-ear disease, of trauma, of primary focus of pus, caused that, the easiest explanation of the symptoms and course of his illness to be rejected.

Post-mortem examination was made on the day after death, and the following notes were dictated. Well-nourished body; skin dark. There is some dense edema of the legs, and on the shins a copper-colored, diffuse eruption, with small superficial scars.

Scalp and calvarium are normal; also bone, dura, and sinuses at base of skull. Dura mater is somewhat adherent to convexity of cerebral hemispheres. Beneath the pia arachnoid covering the lower surface of the cerebellum there is a diffuse movable collection of about a dram of greenish-yellow pus. Arachnoid in that situation is opaque, thickened, and wrinkled. Base of brain is normal, except for some overfulness of the vessels. Island of Reil is normal on both sides. Vessels of pia arachnoid over convexity generally are filled with dark blood. Over parietal lobe of left side, pia arachnoid is adherent to brain substance. On handling the brain a rupture took place just behind the supramarginal gyrus, and about an ounce of fetid, greenish, thick pus escaped. The left lateral ventricle filled with greenish pus, and the ependyma is thickened, granular, dark, and almost gangrenous in appearance. The surface of the basal nuclei was softened. On the right side the lateral ventricle and its nuclei were normal. In the third ventricle there was some greenish pus similar to that in the left lateral ventricle, but the ependyma looked quite normal. The iter contained a little pus, as did also the fourth ventricle. The wall of the latter was granular and softened. On section of the hemisphere it was found that beneath the supramarginal gyrus of the left side there was a walnut-sized cavity, with black, gangrenous walls, just beneath the cortex and extending inward and downward to open into the lateral ventricle, and also extending forward and downward into the basal nuclei. On section of the basal nuclei of the left side, it was found that the abscess cavity had encroached upon the lenticular nucleus, the whole lower two-thirds of which were gangrenous. All of the basal nuclei on the left side were distinctly softened. Organs of abdomen are in normal position. Pleural cavities are normal and free from fluid and adhesions. Pericardium is normal.

Primary section of the heart shows that all chambers are filled with clots. In all chambers there is much chicken-fat and currant-jelly clot, but there is also a small quantity of adherent *ante-mortem* clot. Heart is globular in shape. Apex is made up of right ventricle. Large proportion of the total bulk of the heart is composed of the right auricle. Coronary arteries are very prominent. Weight of heart, when freed from clots, is fifteen ounces. Muscle-substance of all chambers is of a deep brown. Right auricle is tremendously dilated. Appendix of auricle is also much enlarged. Thickness of wall of right auricle at thickest part is about 2 mm. Endocardium of auricle is smooth. Foramen ovale patulous, admitting the end of a lead-pencil. Immediately below the foramen ovale there is a deficiency in the interauricular septum, leaving an arched entrance from the right to the left auricle, that permits of the insertion of the index-, middle-, and ring-fingers. The arch is evidently composed of muscle-fiber; its edge is smooth and rounded, and the surrounding endocardium is thin, clear, and otherwise normal in appearance. The orifice in the septum is bounded below by the lines of attachment of the anterior mitral and posterior tricuspid leaflets. On looking into the right auricle from above, one sees the auricular surfaces of the mitral and tricuspid valve leaflets, and also through the deficiency the posterior wall of the left auricle. The left auricle is very much smaller than the right, being even somewhat smaller than normal. On looking into it from above, one sees the patulous foramen ovale; below this the arching border of the interauricular opening and the interior of both right and left ventricles is plainly to be seen. The auricular appendage communicates with the cavity of the auricle by an orifice that just engages the tip of the middle finger. The right ventricle is much dilated and its wall hypertrophied. The muscle-substance is somewhat darker than normal, but is otherwise of normal appearance. The thickness of the wall is 13 mm. Columnæ cornæ are very thick and firm. Two large papillary muscles spring from the septum, and a diminutive one arises from the anterior wall. The tricuspid orifice readily admits four fingers. Valve leaflets of tricuspid normal, except for their extraordinary largeness. The chordæ tendineæ of the tricuspid valve are remarkably numerous and very thick. The undefended space is closed merely by the posterior tricuspid and anterior mitral leaflets. The finger readily passes from the channel of the tricuspid into that formed by the mitral leaflets, and the finger so passed through the interventricular deficiency is plainly seen on looking down into the auricles. The pulmonary artery cusps are very large, but are otherwise normal in appearance. The pulmonary orifice measures 10 cm. 1 mm. in circumference. The aortic orifice measures 7 cm. 6 mm. in circumference. The cavity of the left ventricle is relatively small—about two-thirds that of the right ventricle; its wall measures 7 mm. in thickness. Endocardium appears to be normal. There is but little development of the columnæ cornæ. There is only one well-formed papillary muscle, which springs from the posterior wall, is short and very thick. This sends three short, thick chordæ tendineæ to the posterior half of the anterior mitral leaflet and two to the posterior leaflet. The other chordæ to the latter spring from two rudimentary papillary muscles that arise from the posterior wall. The anterior portion of the anterior mitral leaflet stretches across from the chordæ already mentioned as arising from the papillary muscle, and is pushed through

the deficiency in the septum in such a way that upon looking at the edge of the deficiency from the right ventricle, there are seen several short chordæ tendineæ rising from the right side and edge of the septal border and running through the orifice to join the anterior portion of the anterior mitral leaflet. Both of the mitral leaflets are somewhat opaque. The aortic orifice is guarded by three cusps, all of which are freely perforated near their free borders. The cusps otherwise show nothing out of the way. The coronary arteries spring from the root of the aorta in the normal position, the orifices being very large. At the root of the aorta there are a few scattered patches of yellowish-white thickening. The importance of a thorough examination of the arch of the aorta and its branches and of the pulmonary artery was not realized until after the heart had been taken away for more careful study, when it was too late to make a further examination.

Sections of the vermiform appendix show a marked amount of submucous round-celled infiltration generally, while in one area the center is necrotic, and evidently has proceeded to abscess-formation. The kidneys show diffuse round-celled infiltration of the interstitial tissue.

To first dispose of the cerebral abscess, it is possible that it may have been due to embolism from the vermiform process, although it seems an unlikely situation for a solitary embolic manifestation from disease of that portion of the intestinal tract. There was no other possible source of origin for the pus. From the character of the collection in the brain, it was thought to be probably due to disease of the middle ear, but careful examination of the base, and especially of the petrous bone, showed no evidence of disease. It is possibly only a coincidence, but is at least a remarkable fact, that at the last meeting of the American Pediatric Society three cases of abscess of the brain occurring in the subjects of congenital heart disease were mentioned. One case was reported by Acker of Washington and one by Jacobi of New York, while the subject of the present article was referred to by the writer in the discussion upon these two cases.

The lesion of the heart in this case resembles, in most respects, the not extremely unusual one of patulous foramen ovale, deficiency of the auricular septum, and deficiency of the ventricular septum at the undefended space. The most remarkable features are the large size of the pulmonary artery as compared with the aorta, and the peculiar arrangement of the anterior mitral leaflet, whereby it receives most of its chordæ tendineæ from the right edge of the border of the septal orifice.

While the dissection of the distal portions of the great vessels was not carried out, it would seem that the specimen represents a failure of development—an agenesis—pure and simple, rather than a permanent defect produced by inflammatory lesion preventing the normal separation of the cavities. It is impossible to see why such extensive failure of achievement of this separation should occur where a much smaller amount of communication between the cavities has been ordinarily produced by even extreme stenosis of one of the arterial orifices of the heart. It seems that the deformities present in this case can be readily explained by a failure of the commissural band to form by fusion of the median parts of the auriculo-ventricular lips of Lindes, with simultaneous failure in development of the primitive interauricular septum and of the median portion of the interventricular septum. The ventricular septum is completed toward the end of the eighth week; the auricular septum forms only after the completion of the separation of the ventricles and that of the arterial bulb. The formation of the commissural band also occurs after the completion of the latter. It can, therefore, be seen that the time at which this anomaly was produced was just prior to the completion of the interventricular septum, and at a time when the primitive auricular septum was simply represented by a ridge coursing over the ceiling of the common auricle.

The failure of development of the commissural band would account for the peculiar complete absence of separation between the anterior mitral and posterior tricuspid leaflets. Rokitansky[1] has likened the auricular canal after the formation of the auriculo-ventricular lips to a figure shaped thus: ⊢—⊣, the long horizontal arm of which represents the space between the surfaces of the auriculo-ventricular lips, the shorter perpendicular arms representing the future auriculo-ventricular orifices.

According to Moussons,[2] the relations of the auriculo-ventricular valve leaflets in cases of failure of development of the interauricular septum may fall into one of three categories: (1) The auriculo-ventricular valves remain in relation with the inferior border of the incomplete interauricular septum; (2) they may be inserted upon the superior border of an incomplete interventricular septum; or (3) they are only attached to the commissural band, which has maintained its independence. In the present case the anterior mitral leaflet is divided into two portions—an anterior, springing from the common auriculo-ventricular border and with chordæ tendineæ, which arise from the right side of the interventricular septum and pass through the deficiency therein, and a posterior portion, which arises from the auriculo-ventricular border and has chordæ tendineæ springing from the poorly differentiated posterior papillary muscle. Between these two portions there is a cleft corresponding to the plane of the incomplete septa and, therefore, to the position that should be occupied by the commissural band. The small size of the left ventricle in the present case is very striking, the septum protruding into its cavity, *i.e.*, the septal surface viewed from the left ventricle, is convex. Upon the left ventricular surface of the septum there is a thickened layer of muscle-fiber, looking not unlike a flattened and poorly developed papillary muscle. Taking into account the position of the septum, toward the left side of the heart, this flattened, aborted papillary muscle on its surface, and the origin of the anterior portion of the cleft anterior mitral leaflet from its upper and uncompleted portion, it seems not unreasonable to attribute this malposition of the leaflet and the small size of the aorta (as compared with the pulmonary artery), with the lessened capacity of the left ventricle to the origin of the ventricular septum from a point too far toward the left, rather than to con-

[1] "Die Defecte der Scheidewände des Herzens," p. 68.
[2] "Maladies Congénitales du Cœur."

sider the small size of the left ventricle as dependent upon the small dimensions of its arterial trunk. In view of the absence of careful study of the subsequent character and the main divisions of the aorta and pulmonary artery, it is impossible to deny a transposition of the divisions of the arterial bulb as the causal factor in the case, but the latter explanation seems to the writer to be less satisfactory than does the former.

In regard to the duration of life in lesions of this character, but little need be said, inasmuch as the principal defect (deficiency in the formation of the auricular septum) is the congenital lesion that is least incompatible with life, save in cases where there is simple failure in the complete development of the interventricular septum at the undefended space. That auricular defect can exist for many years, is seen by the following brief summary of facts:

Peacock[1] says: "Where there is only some slight irregularity in the development of the heart, so that small openings exist in the septa of the auricles or ventricles, the defect is of very little importance; indeed, it is by no means uncommon for such openings to be found in the hearts of persons who have died at advanced periods of life, and have never presented any signs of cardiac disease. On the other hand, where the arrest in the development of the heart is more extensive, and is combined with some form of obstruction, it becomes a source of serious suffering, and the duration of life is limited to a comparatively short period." He gives no definite data as to the length of life of cases with marked septal deficiency, and it would seem that in the above sentence he refers rather to the cases of slight communication between the cavities, as in the case of unclosed, undefended space or patulous foramen ovale, than to such marked deficiency of separation as was present in the specimen from my case.

Moussons[2] groups all cases from a prognostic point of view into eleven classes, of which but one—composed of malformations of the interauricular septum—in any way corresponds to this specimen. In this group he collects 19 cases, of which 5 died between the ages of thirteen and twenty years; 6 between twenty and twenty-five years; 5 between twenty-five and forty years; and 3 between forty and fifty years. In this table no statement is made as to the size of the orifice between the auricles, a factor that cannot fail to have much bearing upon longevity. In a heart wherein the primary auricular septum was completely developed, with simply a cribriform arrangement of this, due to failure of development of the secondary interauricular septum, there might be but little commingling of the blood-stream or alteration in the dynamics of the heart.

Rokitansky[3] relates details of twenty cases of defect of the interauricular septum of greater or less degree. Of these twenty cases, two newborn and eighteen adults were the subjects of the anomaly. The ages of the adults varied from nineteen to sixty years. As many of these present marked points of similarity to the present case, a brief account of some of them may be not without interest. In Case I, a man dying at the age of fifty-five years with a variety of lesions, including tuberculosis of the lungs, an apparent internal pachymeningitis, and a variety of other lesions unconnected with the cardiac anomaly, there was an interauricular communication, having a diameter of 28 mm., and due to defect in the primary septum. Case II was an adult (age not stated), whose heart presented a rudimentary interauricular septum, a closed foramen ovale, and a split aortic leaflet of the mitral (as in my case). The interauricular orifice measured 30 mm. in diameter. The man had in addition pericarditis, purulent exudate in the right pleural cavity, ascites, and anasarca. A drawing of the auricular defect in this case[1] fairly represents the appearance in my own case, save for the closure of the foramen ovale. Case III died of typhus at the age of twenty-three years, the heart showing an orifice between the auricles that measured 18 by 28 mm., and a split anterior mitral leaflet. Case VI concerned a sixty-year-old man, whose body showed, in addition to the cardiac anomaly, the remains of an encephalitis. The interauricular communication measured 9 mm. by 5 mm. The case is mentioned here because of the apparent similarity between this and the writer's specimen in regard to the peculiar connections of the aortic leaflet of the mitral valve with the defective septum ventriculorum. Case VIII died at the age of fifty years, and autopsy revealed, in addition to many small hemorrhagic cerebral lesions and pulmonary artery thrombosis, an interauricular defect measuring 57 mm. in diameter. Case X died at the age of forty-two years, and possessed an interauricular defect that measured 40 mm. in diameter. The case died with universal edema, but from the data given it is impossible to determine the influence of the cardiac defect upon the length of life. The other cases either died at a much earlier age or had but little in common with my case from an anatomical point of view.

The facts in my case may be summarized as follows: Clinically, the case is of interest from the fact that the patient apparently suffered so little from a marked cardiac defect that he was able to perform the arduous duties of a sailor until the onset of a presumably independent cerebral lesion, eighteen days before his death; from the occurrence of a cerebral abscess, the only discoverable source of origin for which was the inflamed vermiform appendix. Pathologically, the interest in the case lies in the great lack of development of the septum atriorum, the smallness of the left and large development of the right side of the heart, and the peculiar arrangement of the anterior mitral leaflet and of the chordæ tendineæ of the anterior portion thereof.

A CASE OF ANGIO-NEUROTIC EDEMA.

By NORMAN C. YARIAN, M.D.,
of Cleveland, O.;
House Physician to Cleveland General Hospital.

On May 1, 1895, I was called to see Mrs. K., who was suffering from a severe "sick spell," as she termed her periodical attacks. I found her vomiting and retch-

[1] *Loc. cit.*, p. 37.

ing in the most violent manner, and doubled up on the floor from severe pain, which she located in the epigastric region. The vomited matter was mostly biliary. Her hands and face were very edematous; her pulse weak and rapid, while her moans were audible at some distance.

The picture was one of seeming great agony, and yet I felt that there was a nervous element in her trouble. I knew of her having had the attacks from childhood, and being unable to make a diagnosis at that time, I treated the case symptomatically.

My prescription was morphin ⅙ grain, atropin $\frac{1}{180}$, hypodermatically, with bismuth subnitrate, ipecac, and calomel in small doses by mouth, followed after vomiting had ceased by moderate doses of calomel, to unload the bowels and stimulate the kidneys to more active secretion, and sodium bicarb. She soon experienced relief.

I was called at several subsequent attacks and always gave the hypodermic, but sometimes changed the other prescriptions. Thinking the trouble at least partially a nervous one, I prescribed strychnia $\frac{1}{60}$ grain three times a day between the attacks, followed by a general tonic of nux vomica, gentian, and cascara for her constipated habit. This medication seemed to make the attacks lighter and less frequent while taking it, but had no lasting effect. Nor did a course of syrup hypophos. co. give any permanent relief.

Her history, both personal and family, is of interest, showing the hereditary and nervous nature of the disease.

History.—Mrs. K., aged fifty-four, American, married, two children, both girls; oldest died at age of twenty-one from tuberculosis; showed no symptoms of mother's disease except a very irritable disposition. Other daughter living, aged twenty-five, is the mother of a healthy daughter. Neither mother nor child have shown symptoms of the disease except the same irritable dispositions.

Mrs. K. relates that while she was still a child, her mother noticed periodical attacks of blanching of the surface of the skin and vomiting. She cannot remember a time when she has not suffered from these periodical attacks of edema, following by gastralgia and vomiting.

The attacks begin by a general feeling of malaise or pain, soon some part of the body, usually the hands, face, feet, arms, shoulders, or chest, will begin to swell and become very edematous. Often, simultaneously with the edema, occur purple rings upon the chest, neck, arm, and hypogastric region. These, however, more often occur just as the edema subsides. Mental emotion, particularly anger, is capable of precipitating an attack, and they often occur with great suddenness. Her appetite is often ravenous and erratic just before an attack, but nothing she eats seems to influence the attack or precipitate it. From twenty-four hours to two days after the swelling begins she is taken with a severe distinct pain, usually in region of the stomach, but sometimes in the bowels. She describes it as being very severe, even terrible and prostrating. This is followed by nausea and vomiting, with severe retching. After freely vomiting, her pain and edema leave, an attack in the morning often failing to incapacitate her for labor in the afternoon.

The attacks show a marked periodicity, occurring on an average of once in two weeks since her child-bearing period, but previously every week for several weeks, then skipping several, nine weeks being the longest period of immunity which she has ever enjoyed. The edema sometimes occurs without the vomiting and pain. The attacks are always more severe when occurring at a menstrual period, and they were also more severe during her menopause.

The patient had the attacks regularly during both gestations.

Family History.—Mother had same attacks from childhood, but not so severe. Never had them during periods of gestation. Died at the age of sixty-three years of dropsy. (Could not learn the cause.) After menopause, she suffered from purpura, and her attacks grew lighter, occurring every two to six weeks. Patient's two brothers and one sister not affected. Uncle on mother's side had same attacks. He looked like his mother and grandfather. Died at age of forty-two of edema of glottis. One other uncle and aunt well. Deceased left one child, a girl, who has periodical edema, but no gastralgia nor vomiting; also one boy who had edema, but died at age of seven years of scarlatina. Grandfather (on mother's side) and some of his brothers had same periodical edema, but lacked the pain and vomiting. Great-grandfather (on mother's side) had same edema, but none of the other symptoms. The attacks have grown worse from generation to generation up to the last two, which have so far proven immune.

There is a marked nervous element in the attacks as shown by the sudden oncome and also sudden disappearance. Their effect upon her general health and strength is very slight, and will perhaps only slightly influence longevity.

No physician has ever been able to influence the disease in any of the successive generations, except for a very brief time.

NEW APPARATUS.

A SIMPLE AND EFFECTIVE SPLINT FOR THE TREATMENT OF HIP DISEASE.

BY AP. MORGAN VANCE, M.D.,
OF LOUISVILLE, KY.

FOR the past fifteen years or more I have been using a short fixation splint in the treatment of hip disease, made of the fine saddle skirt leather, molded over the patient and made removable by lacing, crutches with high shoe being necessary for locomotion. The advantages claimed for this splint were its lightness, cleanliness, durability, and the fact of its easy removal; besides, it could be prepared without the aid of an instrument-maker, and could be worn effectively without the constant care of the surgeon. Therefore it served an excellent purpose in those cases which came from a distance for treatment. The great disadvantage in the use of this very simple apparatus was found to be the tendency on the part of the little patients to lay aside the crutches in the excitement of play and walk on the diseased limb, notwithstanding the hampering influence of the high shoe on the affected side.

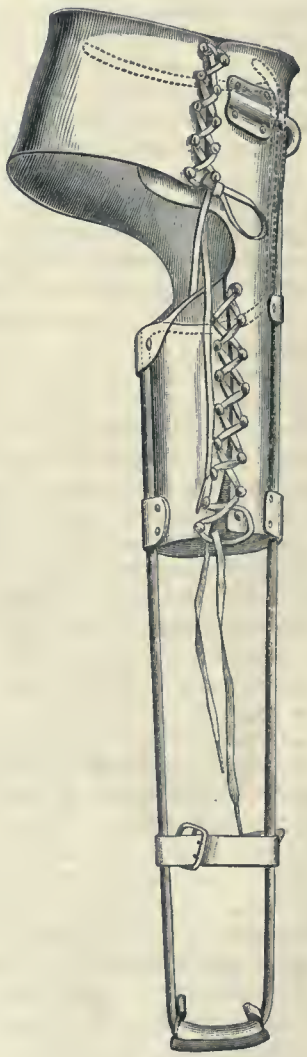
My friend Dr. J. B. Bullitt, of this city, suggested to me the trial of the splint used by Lorenz, of Vienna, which is a plaster-of-Paris splint, reaching from the umbilicus to just above the ankle, combined with a stirrup of strap-iron under the foot, a high shoe on the good foot, the weight of the body resting on the ischium, where the splint was furnished with a good pad. The idea which I had entertained for a long time of making my splint a walking apparatus was stimulated by a trial of the plaster-of-Paris splint of Lorenz, and I made the effort in November of 1895. Instead of the strap-iron as used by Lorenz for the stirrup, I used a small, solid brass rod, a material I had employed for a long time for knee-splints and paralytic apparatus. The very satisfactory use of the apparatus resulting from this first experiment, along with some dozen other cases to which I have since applied it, influences me to give it to my professional brethren, with a short description of the method of its construction, illustrated as best I can with cuts.

The original leather fixation splint referred to is made as follows: If there is deformity present, or an acute exacerbation in the joint, a weight and pulley are applied and the child kept in bed for a few days or weeks, as may be required; then the piece of leather is cut from a side of the best saddle skirting, after a pattern of paper which has previously been fitted to the patient. The shape of this is represented in the outline drawn in Fig. 1. When this is molded — which is made very

Fig. 1.

easy by immersing the leather in hot water until well wetted through, the temperature of the water regulating the stiffness of the splint when dry, a few degrees below boiling making it about right, an ordinary roller, or better an elastic bandage, is used to mold it to the patient—it extends from the umbilicus to the knee, the leather being so cut and placed as to bring the lacing of the thigh and pelvic portions in front. Two nicely trimmed tongues of the same leather are cut from the flank part and riveted on with a tubular riveting machine, large shoe-hooks having first been placed along the outer edge of the part to be laced. A special tool is required for this; or the lacing may be done through simple holes made with the ordinary leather- or belt-punch. It is best to put the hair or smooth side of the leather next the skin; then, ordinarily, nothing need be worn between the splint and the body. While this leather portion is allowed to set, not to dry, an outline drawing is made of the splint in position and the leg below, care being taken to locate on the paper the upper edge of the splint, the ischium, lower edge of the splint, bottom of heel, and a point 2½ inches below the heel. This drawing will be needed as a working pattern to be used in properly bending the brass rod, which will make up the balance of the apparatus. A solid brass rod from one-quarter to three-eighths of an inch in diameter, the length necessary being determined by measurements of the special pattern, is bent so as to be

Fig. 2.



applied to the splint of leather in such a way as to extend from the front of the pelvic part of the splint down the outer side of the limb, under the foot, up the inner side of the limb to the ischium, around to the outer side of the splint, to meet again about the trochanteric region, up the outside of the pelvic part, and back to the middle of the pelvic portion behind. This brass frame is then fastened to the leather by leather battens riveted through and through with tubular rivets, a smooth pad of leather

being fitted over the rod and leather so as to form a firm rest for the seat-bone. A leather band below to fix the leg, and a leather sole with arrangement for attaching extension, if needed, complete the apparatus, the whole being covered with a thick coat of shellac if the child is in the habit of wetting the bed.

Fig. 2 shows the splint complete. The great durability and firmness of this splint, along with the fact that it is easy of removal and that it cannot be improperly applied, coupled with the fact that it can be made by the surgeon himself, and fills all the mechanical indications in the treatment of this most troublesome disease, make it, in my humble opinion, one of the best mechanical contrivances yet proposed. The comfort with which the little patients are immediately able to walk about, and the simplicity of its construction, with its cheapness, will recommend it for a trial.

MEDICAL PROGRESS.

Intestinal Sand and Muco-membranous Enteritis. — In two cases mentioned by MATHIEN and RICHARD (*Gaz. hebdom. de Méd. et de Chirurg.*, May 28, 1896), the feces were mixed with grains of yellow sand, one-quarter to one-half millimeter in diameter. In one case, the grains were often agglutinated, and formed masses much resembling white pepper kernels. In their composition, the salts of lime predominated, and in this they resembled the calculi sometimes found in the appendix, intestine, nasal passages, bronchi, etc. In both cases mucoenteritis was present, which the authors looked upon as the cause of the concretions, as the membranes contained microscopical crystals of calcium phosphate. The abnormal deposit of these crystals in the mucous membrane would, it was thought, cause mucoenteritis, and the stasis due to constipation, would allow the formation of the palpable grains of sand.

Others have mentioned the coexistence of mucoenteritis and intestinal calculi.

Removal of One-half of the Kidney for Tuberculosis; Favorable Prognosis in Renal Malignant Disease.— How important has become the application of surgery to the kidney, is shown by the fact that a single operator, J. ISRAEL of Berlin, is able to report (*Deut. med. Woch.*, May 28, 1896) 126 cases so treated by himself. Eleven times the kidney was extirpated on account of tubercular disease. In a twelfth case, the lesions were situated so evidently in one end of the organ that Israel decided to remove only the upper half of it. Hemorrhage was avoided by digital compression of the renal artery during the cutting away of the diseased portion. Then a compress was held against the cut surface for some minutes; upon its removal there was no bleeding, but for safety, a piece of gauze was stitched by catgut against the cut surface. Recovery was prompt and complete, and the patient has remained in good health for over a year.

This operation is recommended only in exceptional cases, as tubercles too small to be observed at the operation usually extend beyond the area of the gross lesion.

Another encouraging feature of this report is the chapter on malignant tumors of the kidney. There were seventeen such cases—six carcinomata; ten sarcomata, and one so-called struma renalis. Complete nephrectomy was performed in each case. Two patients died from operation; one a year later, of acute peritonitis, without recurrence of the cancer, and six were well at the time of report, no recurrence having manifested itself in periods ranging from fifteen months to nine years.

Chlorosis No Contraindication for Marriage.—The question which is often put to the physician as to whether a chlorotic girl ought to marry, has been fully discussed in a monograph by GROSSET (*Thèse de Paris*, Steinheil, 1896). His conclusions are :

1. The physical and spiritual excitement which marriage offers a chlorotic girl can have only a favorable effect upon her disease.

2. The sterility of chlorosis is only a temporary one in most cases, the rare instances of infantile genitals being excepted.

3. Chlorosis does not predispose to abortion.

4. The children of a chlorotic woman are likely to be chlorotic, but seem to show little tendency to become tuberculous.

Chlorosis, therefore, is no contraindication for marriage.

Tumor of Mesentery; Tubercular.— In the *Deut. med. Woch.*, June 11, 1896, GRUNEBERG mentions a rare case of tuberculosis isolated in the mesenteric glands, and resulting in an abscess holding about two pints, which formed a freely movable tumor in the right side of the abdomen, the site of which was correctly diagnosed, but whose nature was not suspected until it was ruptured in the attempt to shell it out of the mesentery. The patient was an eight-year-old girl, with no previous illness except a diarrhea of short duration three months previous to the appearance of the tumors. At the autopsy, three days after operation, other mesenteric glands were found tubercular, but there were no other traces of tubercle organ.

Technic of Esophagoscopy.—V. HOCKER (*Wiener klin. Wochenschr.*, 1896, Nos. 6 and 7) uses a Mikulicz-Leiter instrument with a small incandescent light. The tubes have a caliber of from 11 to 14 mm., and are 19, 30, 40, and 45 cm. long, corresponding to the usual situations of cancer at the beginning of the esophagus bifurcation of the trachea, lower end of esophagus, and cardiac end of stomach. Hocker begins the passage of the instrument with the patient in a sitting posture, but allows him gradually to recline on his side with his head over the edge of the table. Cocain in the pharynx is better than morphin, and controls the flow of saliva. In two hundred cases no accident has resulted; in two cases, the instrument could not be passed.

The Mortality After Removal of the Scapula.—SCHULTZ has made a study of the 214 cases recorded in medical literature in which the whole scapula was removed, either alone or with the arm and part of the clavicle. The results as published in the *Deut. Zeit. f. Chirurgie*, vol. xliii, p. 442, are worth knowing.

REMOVAL OF SCAPULA ALONE.

	Cause.	No. of Cases.	Mortality, Per cent.
Before 1875.....	Malignancy.	23	17.39
After "	"	28	7.14
Before "	Caries, etc.	8	12.50
After "	"	14	....
.....	Injury.	17	52.94

REMOVAL OF WHOLE UPPER EXTREMITY.

	Cause.	No. of Cases.	Mortality, Per cent.
Before 1875.....	Malignancy.	26	19.23
After "	"	69	13.04
.....	Caries, etc.	7	.....
.....	Injury.	22	36.36

From these tables it is evident that the prognosis after this formidable-appearing operation is much better than might be expected. The percentages of recurrence after operation for malignant tumors are less satisfactory. These are given as 35 and 28 per cent. before and since 1875, where the whole shoulder was removed, and 39 and 19 per cent. in those cases where the scapula alone was removed, before and since 1875.

THERAPEUTIC NOTES.

Hemol Bromid.—In order to avoid the unpleasant after-effects of the inorganic bromids, KOBERT (*Therapeutische Wochenschrift*, 1896, No. 17, p. 400) has been making trial of an organic bromid which has no injurious effect upon either the blood or digestion. It contains only 2.7 per cent. of bromin, as against 67 per cent. which bromid of potassium contains. But only a small portion of the bromin contained in the latter salt exerts any action in the body.

Holst used bromid of hemol in fifty cases of nervous disease. If a rapid effect was looked for, two grams (thirty grains) were given three times a day. One-half or one-third of this dose was employed for a calming effect, In epilepsy and hysteria, he obtained no good results where the inorganic bromids have shown themselves efficacious. In insomnia, the results were equal to sodium bromid, without any unpleasant sequelæ.

The conclusion is that bromid of hemol is not capable of replacing inorganic bromids where a rapid effect is desired. It is indicated, however, in cases where the sedative and long-continued action of bromin is sought for.

Abortion from Guaiacol.—A woman twenty-nine years old, and three months pregnant, was given (PETRASKO, *Pesther med. Chir. Presse*, 1896, No. 5) at morning and noon three-quarter grain of guaiacol on account of an affection of the left pulmonary apex. On the sixth day, when about twelve grains had been taken, the patient aborted. The physician could find no other reason for the abortion except the guaiacol.

Influence of Somatose on Milk Secretion.—The diminution or disappearance of the mother's milk in a few months or perhaps in only a few weeks after her child is born, is a source of annoyance and pain to the mother, and may prove fatal to the baby. It is no wonder then that DREWS of Hamburg, feels happy over the results which he has been able to obtain with somatose, and which he describes in the *Centralblatt f. Innere Medicin*, June 6, 1896. He has given the drug in teaspoonful doses, three or four times a day, to twenty-five women who experienced premature exhaustion of breast milk, caused by anemia or by loss of blood during pregnancy or labor, or by debility from frequently repeated parturition, or by intercurrent diseases. In every case the secretion of milk became sufficient for the baby, and the pains in back and breast disappeared.

The results could not be attributed to anything else than the somatose. The diet was not an especial one. Many of the patients had been treated with tonics and other remedies without avail. It was further shown that when the somatose was cut off, in a very short time the milk began to diminish, and the pains returned, even though the appetite and general health were in no way affected.

Arsenic by the Rectum.—VINAY (*Lyon Méd.*, April 12, 1896) prefers to administer arsenic by rectal injection, for the reason that despite every precaution, subcutaneous injections are apt to be followed by abscesses, and because arsenic, given by the stomach, for a long time upsets the stomach and takes away the appetite.

He uses a mixture containing one part of Fowler's solution and fourteen parts of water, of which he injects at first 80 ♏ (5 grams), morning and evening, and later the same dose three times a day. This treatment may be continued a long time without causing rectal tenesmus. The sole contraindication is a possible diarrhea.

Action of the Stomach During Sleep.—Examination of the contents of the stomach obtained in sleep, have convinced SCHULE (*Berl. klin. Woch.*, 1893, No. 50 and 51) that the acidity of the stomach is greater during sleep, and that its motility is lessened. Persons with digestive trouble, therefore, especially if hyperacidity is present, ought not to sleep after eating. Instead, the meal should be followed by wakeful repose.

Successful Laparotomy for Ruptured Uterus.—Three hours after labor began in a twenty-one year old, III-para, the membranes ruptured and a hand came down. Two hours later, a midwife made desperate attempts to extract the child by this arm. There was a sudden pain and collapse, with pulse of 128. About two hours later, the abdomen was opened, and the child and placenta found in the peritoneal cavity, the rupture being on the anterior wall of uterus and vagina, and extending into the left broad ligament. The uterus was removed, and its stump treated extraperitoneally.

According to REIN (*Wratsch*, 1896, No. 6), whose case this is, laparotomy has been performed in rupture of the uterus twenty-five times, fifteen times successfully.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

SATURDAY, AUGUST 29, 1896.

THE PRESENT ADMINISTRATION AT QUARANTINE.

In a position so important as that of health officer of the great port of New York, with duties and responsibilities so delicate, it is peculiarly fitting that the professional public should keep well informed as to what is going on, for in the successful management of the office the medical profession, as well as the public at large, is greatly concerned. Indeed, a mistake here may prove very costly, as history of no very remote date will show; and the entire medical profession will then come in for a share of the blame, which the dear public is ever ready to bestow upon the unsuccessful office-holder. The present administration has clearly taken advantage of certain errors and omissions of the past, and has brought its work to such a high degree of efficiency that to withhold approval would be simply to ignore good work and honest endeavors.

The health officer and his deputies, when on duty, are in uniform; and this, it strikes us, is a distinct gain in the way of producing a good impression upon those with whom they are brought into official contact. The uniform is the badge of authority, and its presence must impress with the majesty of the law among us those who visit our shores for the first time.

The official headquarters, which were destroyed by fire some months ago, are being replaced by a commodious and tasteful structure, which will soon be completed. Within this building, in addition to offices for general business, will be located a bacteriological laboratory, which is already fully equipped in temporary quarters. The meaning of this laboratory to a conscientious official, and the additional security which the public obtains thereby, cannot be overestimated. A suspicious case of disease appearing upon a ship, a bacteriological examination of the secretions or discharges reveals its character in a few hours with unerring determination, and decides whether the ship may proceed on her way to port or be detained with her passengers and cargo. This fact is not usually appreciated by the general public, and the solution of this question of delay by the present health officer certainly reflects the greatest credit upon him. If a ship arrives after sundown, instead of being obliged to lie at anchor for the night in the lower bay, she is inspected at once and allowed, if in suitable condition, to proceed to her berth. If there are immigrants or others requiring individual inspection, an electric search-light is set up upon the deck, and under its powerful beams the inspection is satisfactorily accomplished. If passengers or cargo require disinfection, the boat, which the health officer has just had constructed, will accomplish it *tute, cito, et jucunde*. A row of bathrooms on either side of the boat will quickly disinfect eight persons by spray or vapor, or both. Clothing, bedding, etc., is all disinfected by steam, *in vacuo*, in a great car, such as is in use by the Board of Health in this city. The cargo itself is disinfected by sulphur gas, which is carried from the disinfecting boat in pipes, under pressure, and distributed where needed, as water is distributed with hose. Thus, a ship, her cargo, and her crew, coming from an infected port could, in a few hours, be sent into the harbor with a clean bill of health, the safety of the public being assured and the rights of the shipping-master protected as well. Surely this is a prodigious advance over old methods.

Should a ship come to our shores, containing many cases of infectious disease—cholera, for example—there would be no long and vexatious detention of the well and clean, together with the sick. The former, after disinfection, would go on their way, and for the latter the health officer has provided large and commodious barges anchored near the quarantine islands, isolation being thus complete and the conditions as favorable as possible for recovery. Of course it is to be hoped that this system may not require the severe test of experience, but if it should, we see no reason to doubt its efficiency. If successful, it would redound primarily to the great credit and praise of the present health officer; it would also be a demonstration to the public that its safety in sanitary matters depends largely upon the endorsement and support of the medical profession.

COMPARATIVE PATHOLOGY.

In these days of the multiplication of special fields in medicine, heavy is the responsibility of the man who dares to add one additional acre to the already continental area which must be kept under cultivation. And yet, this is what appears to have been done in the establishment of chairs of Comparative Pathology by the University of Buffalo three months ago, and by Harvard a few weeks later. The addition, however, is more apparent than real, as the new field is to be opened up not so much in search of new facts as for the purpose of finding a key to many of the facts and problems already in our possession. The aim of the new work is mainly to find the physiological prototype and ancestor of our human pathological processes, or that simpler form of disturbance of metabolism out of which have grown our own more complicated disease-processes. To this end the enormous mass of facts already reported by zoölogists, botanists, vegetable pathologists, veterinarians, and agriculturalists, now scattered through a dozen fields and languages, and a hundred journals, must be collected and classified for the use of the human pathologist, and even though the search for the physiological type of human disease be as fruitless directly as that of Ponce de Leon for the fountain of youth, yet like it the fertile continent it traverses cannot fail to be productive of rich returns in other directions.

Another question upon which new light is to be hoped for, is the dependence of disease upon the structure and developmental history of the part or organ affected. Disease, of course, is simply life out of place, health run mad, pathologic action a mere excess or deficiency of physiologic action, and the varying degrees of development of a given organ in different species can often be shown to determine the disorders to which it is most liable. For instance, the mammalian stomach is essentially a mere sacculation, a local distention in the course of a simple, primitively uniform alimentary tube. Let this distention pass a certain point, however, and we have at once gastric dilatation, (gastromegaly) one of the most obstinate, distressing, and frequent morbid conditions of the organ in our own species. In the carnivora, however, on the one hand, where this physiologic distention has not progressed so far, pathologic dilatation is rare, while in the herbivora, on the other hand, it is not only extremely common, but frequently and rapidly fatal, either from rupture of the already (normally) distended viscus, or from embarrassment of both respiration and circulation by pressure upward of the diaphragm. Again, in the case of the cæco-appendix, appendicitis in the human subject is but an acute (septic) exacerbation of a normal process of wasting and atrophy of this part of the gut, which, as Zuckerkaudl has shown, results in nearly sixty per cent. of cases in its occlusion from the rest of the tube before the fortieth year. And of this charming process we have a proud monopoly. The carnivora are exempt for the good and sufficient reason that they have no appendix (although this region is still a *mauvais terre* and typhlitis is not uncommon) while the herbivora are almost equally so, because in them, instead of a mere "vermiform" remnant, there is present a large, well-developed, and fully functional diverticulum, of equal caliber with the rest of the gut. There appears to be but little hope of our ever having wings in this life or the next—except those of us who are born in Philadelphia—but there is a fair prospect that we may one day get rid of our appendices, which would be a more substantial advantage.

Then again, when a human organ is found peculiarly liable to serious disease, and an examination of the same organ in other mammals reveals an almost equal susceptibility, the inference is strong that this can only be explained by something in the common ancestral history. Take, for instance, the case of the lung, which has already been briefly discussed in these columns. (Medical News, January 11, 1896, p. 49.) Disease of this organ is responsible for nearly one-third of all deaths in our own species; the same thing is true of monkeys, apes, and the carnivora, while its "bad eminence" is only slightly less in the herbivora, and in birds. Now the most striking feature in common in the history of all these beings is their comparative recentness, appearing long after every other organ in the body was perfected except the uterus and mammæ. They are the "parvenus," "les nouveaux riches" of the entire body, and hence the least stable, the most easily upset. Furthermore, it is the special regions of this already unstable organ which are undergoing change in form or atrophy that are peculiarly liable to the attack of disease. In the human species it is the right apex, the disappearing "eparterial" lobe, whose presence is attested by the seventh cervical rib in the embryo, in which nearly forty per cent. of all cases of pulmonary tuberculosis have their origin; in the herbivora, the "lower" (posterior) extremity, which is receding before the huge stomach and food-canal, is the commonest site of tubercle.

In cancer the singular immunity possessed by the domestic animals seems most probably explicable on the ground that their sexual functions continue almost as long as life. Uterus and mammæ do not, therefore, become senile atrophying foci for this process of anarchy. This cuts down the possibility of cancer in the female sex nearly seventy per cent. at once, while, as these animals seldom long survive their teeth, the lip does not become a supernumerary organ, and the tongue a site of sympathetic atrophy as in our own species. The few authentic cases of cancer reported in dogs have had the disease located at that common "unsettled" borderland, the pylorus, where the ancestral gastric mill, or "gizzard," is still in process of disappearance.

Acne, also, that abortive effort on the part of our atrophied hair-glands (miscalled "sebaceous") on the most completely denuded parts of our surface, the face and chest, to reproduce at puberty our ancestral hairy covering is practically unknown in any of the lower animals, for the simple reason that they have no denuded surfaces studded with atrophied glands, but all their hair-glands are fully developed and functional from birth or shortly after. It would even seem as if we might hope for some light upon that pathologic puzzle, diabetes, since the essential condition, an excess of sugar in the tissues, has been discovered in certain plants, notably English violets, causing marked edema and a high degree of susceptibility to the attack of a certain fungus which rapidly proves fatal. Similar results were produced in control-plants by the injection of solutions of maltose into the fibro-vascular bundles at the stem. From which it would appear that even "sweet violets" may actually become "too sweet to live."

An interesting, if somewhat misty, field for comparative study is that presented by the nerve branches which are under "anatomical strain," viz.: the recurrent laryngeal, and the spinal accessory. The former nerve, whose course was laid when the heart was literally "in the mouth" and the trachea-lung a mere ventral pouch from the esophagus and which was dragged down by the descent of the heart is liable, in our own species, to both spasm and paralysis to a degree which has never been adequately accounted for upon the grounds either of position, exposure, or physiologic wear and tear. In the horse, where the "dragging down" has been much greater on account of the greater proportional length of the neck, it is peculiarly liable to paralysis giving rise to the symptom known as "roaring." This is produced by the friction of the air against the vocal bands which cannot be adequately separated to admit a large enough column of air to supply the animal at a high rate of speed and is actually obviated in race-horses by the introduction of a large tracheotomy tube. Its prevalence may be judged from the fact that in the recent St. Leger stakes no less than four out of fourteen starters, among whom was the winner, wore silver tubes in their tracheæ. In the great majority of

cases it is the left nerve, which passes round the aorta and is thus not only further stretched but exposed to the strain of its heavier pulsations as well, which is affected. Curiously enough, in the giraffe, as Dr. Chapman has reported from the careful dissection of several specimens, this nerve is entirely absent, and the superintendent of one of our largest zoölogical gardens assures the writer that the animal is practically voiceless, or at least that in fifteen years' experience with them he had never known them to make a sound other than a grunt or hiss. One is strongly tempted to connect this singular condition with the enormously elongated neck and consequent "stretching," but it may be merely a coincidence.

There seems to be little question of late that the spinal accessory, with its singularly roundabout course from the six upper cervical roots, up through the foramen magnum into the skull, out through the jugular foramen and down to the middle of the sternomastoid nearly opposite its origin, is principally concerned in the production of that distressing and frequent affection, spasmodic wry-neck. Noble Smith declares that in these cases, "section and ablation of a piece of the spinal accessory nerve is absolutely certain to remove all spasm from the muscles supplied by that nerve and very likely to remove spasms set up in other muscles, although other nerves are apparently involved." Here the "anatomical stretching" is due to the development of the neck and consequent subsidence of the shoulder-girdle from the level of the occipital region, and the extreme liability of this nerve to spasm may be a mere coincidence again.

Then again, in the varying intensities of anemia, from simple to pernicious, we have a most perfect series of reversions on the part of the blood toward the lower vertebrate or even invertebrate type. The decrease of red cells, the marked increase of white, the difficulty of maintaining the body-temperature, the appearance of nucleated and even oval red cells (salamandroid), the increase of uric acid, all point in this direction. This is, of course, the merest outline sketch of lines which it might be useful to follow in this work; others will suggest themselves to everyone. The diseases which are common to or communicable between man and animals, the infections of meat, milk, fish, and vegetables, are of immense interest and importance and are already claiming the attention of a host of skilled investigators. The keynote of comparative pathology is simply that we are a part of all that ever was, that the life of all the ages flows in our veins, and that even in our diseases may be read our pedigree. And its dominant overtone, strange as it may seem, is one of consolation, that the very same processes which make for pain, for disease, and death, also make with tenfold force and frequency for comfort, for health, and for life; that there is no such thing as essential evil in the physical world, whatever there may be in the spiritual.

Woods Hutchinson, M.D.

ECHOES AND NEWS.

Sir Spencer Wells' Successor.—The Queen of England has appointed Mr. Rickman John Godlie, F.R.C.S., Surgeon to the Household in Ordinary to Her Majesty, in place of Sir Spencer Wells, resigned.

Medical Service of the Paris Exposition.—Dr. Gilles de la Tourette has been appointed physician-in-chief to the Paris Exposition, to be held in 1900. There will be an exhibit of objects illustrating the progress of medicine and surgery.

Dr. Samuel Johnson on the Nude in Art.—Dr. Johnson was not a medical doctor, but one of his sayings was worthy of such an one. It was on the nude in notable paintings of his time. "Sir," said Boswell, "do you consider Mr. Opie's naked Venus indecent?" "No, sir," was the answer, "but your question is."—*Boston Herald.*

Hospital Surgeon Suspended.—The Governors of the Sale Hospital, Victoria, Australia, after investigating the complaint of a patient against an honorary surgeon for want of skill and rough handling, voted to suspend him. It was found that, without consultation or trained assistance, the surgeon had performed an operation upon the patient's penis, refusing to use an anesthetic.

Eucain and Cocain Compared.—In a paper based upon an experimental investigation of the relative effects of these kindred drugs, which Professor Charteris presented to the Royal Society of Edinburgh, he concluded that in aqueous solutions of the hydrochlorates slightly larger doses of eucain were necessary to produce lethal effects in guinea-pigs, and its physiological action was slower in onset and less in intensity.

Ophthalmia in Poor-law Schools of London.—The Local Government Board has appointed Dr. Sydney Stephenson

to officially inspect the eyes of 20,000 children in the poor-law schools in its effort to free their wards from the fearful consequences of ophthalmia. In 1874 Mr. Nettleship claimed that eighty per cent. of these children were so afflicted, while at present it is thought the percentage is less than ten.

Gifts to Charity.—By his will, John W. Gadsden, a well-known veterinary surgeon of Philadelphia, has ordered the major part of his estate, valued at $50,000, distributed among the several charities of that city. A special bequest of $5000 is made to establish a free bed, to bear his name, in the Protestant Episcopal Hospital. The apportionment of the remainder is left to the judgment of his executors.

The Penalty in French Quarantine.—Death is the penalty for breaking through quarantine in France, according to a law passed in 1822 and still in force. A peasant from the Pyrenees who had returned from Buenos Ayres in a yellow-fever ship and had scaled the lazaret walls at Pauillac in order to get home sooner, has just been on trial for his life at Bordeaux. Though his offense was clearly proved, the jury naturally acquitted him.

Legal Measures Threatened.—It seems that the Harvard Evening Medical College and Hospital, of Chicago, has, without authority, announced Professor Edwin Klebs, M.D., as occupying one of its chairs. Professor Klebs has warned it that unless the catalogues containing this announcement are suppressed, he will institute legal proceedings. It is against the same college that Harvard University was recently seeking an injunction to prevent the use of the name Harvard.

Hebrew Medical Men and the Moscow Congress.—By reason of the laws of Russia, which discriminate so severely against Hebrews, it was found that all medical men of that race would be prevented from attending the International Medical Congress. A strong communication to the authorities of the Congress, from the German profession, headed by Professor Virchow, has caused the Government to suspend the act as it applies to the visitors to the Congress. It is provided, however, that the passports presented by Jewish members shall be countersigned by a Russian consul.

Antivenene.—One of the most interesting scientific questions of the year was brought to the general notice of the profession by Professor Fraser's paper before the British Medical Association upon the antidotal treatment of serpent poisoning by serum, and perhaps more clearly still, in a lecture upon the same subject by Dr. A. Calmette, of the Institut Pasteur, Lille, before the Royal College of Physicians and Surgeons. The practical value of "antivenomous serum" is already being tested in India, with most favorable preliminary reports.

Privacy for Medical Councils.—A suggestion made by the *Medical Press and Circular* strikes us at this distance as a very appropriate one. It is that hereafter it would be more in keeping with the time-honored dignity of the profession and better for its well-being and good name if all medical societies (the British Medical Association included) would conduct their ethical sections in secret, or at least with such privacy that the lay press would be deprived of the opportunity to magnify their occasionally unsavory or sensational proceedings in its daily columns.

An Overcrowded Hospital.—Dr. John A. Arnold, the medical superintendent of the Kings County Hospital, at Flatbush, is reported to have made the following statement: "No more patients can be received unless we put them on the roof. A condition similar to that existing here cannot be found, probably, in any other hospital in the civilized world. To say that the building is overcrowded does not describe the actual state of things. It is packed with patients from cellar to attic. It has been out of the question to give each patient a cot. We have to place two cots together so as to make one bed, and three patients are crowded into it. We also have beds on the floor. Why, we even are compelled to put the sick people in the basement. Our great city permits 635 charity patients to be crowded into a building that can accommodate only 250 comfortably."

Dark Light.—This is the term employed by a French savant, M. Gustave Le Bon, to denote the photogenic action exerted by the light of a kerosene lamp, an Auer burner, through a sheet of lead, on copper, upon a sensitive plate placed under a negative. The results of the first experiments have since been amply confirmed, and in some instances exceeded by other investigators, especially M. Murat of Havre, who has obtained by this means pictures precisely similar to those brought out under the Röntgen rays. Specimens were exhibited at the last meeting of the Paris Academy des Sciences, and the descriptions read like fairy tales. The most surprising fact in connection with this discovery is that the thickness of the metal or other opaque substance interposed between the light and the negative seems to have no effect upon the success of the photograph.

Pleuritic Fluid Substituted by Saline Solution.—Lewaschev first proposed this plan of treatment at the Berlin International Congress. According to the *Therapeutische Wochenschrift*, June 28th, his subsequent success has been marked, and he feels impelled to recommend his plan in stronger terms. His method, in brief, is to substitute an equal amount of saline solution for the pleuritic effusion, and he has now a record of fifty-two cases, all followed by marked relief and prompt recovery. Thoracocentesis is first performed, and as the effusion is gradually aspirated it is replaced by physiologic salt solution, which prevents too rapid expansion of the organs into the empty pleura, while the solution is gradually absorbed and exerts a general tonic and local antiseptic effect. The journal above referred to devotes ten (10) pages to a complete résumé of the results and technic of this treatment.

Music in a State Asylum.—Dr. Sylvester, superintendent of the Kings County Hospital for the insane, has hit upon the idea of forming an orchestra out of the employees and inmates of the institution. For some time the superin-

tendent has been trying to get up some sort of a diversion for the patients, and he was interested to learn, several weeks ago, that not a few of his patients were both fond of music and capable of its production. He called for recruits from the army of employees and patients, and soon had a band of sufficient number and unexpectedly good quality. Some of the patients lend themselves readily to the new diversion. A young man twenty-eight years old, who suffers from an acute form of delusions, has become an accomplished artist on the tuba. An orchestra of eighteen pieces will soon be organized, and the players will begin regular rehearsals for the winter entertainments. Thus will the monotonous routine of the long winter months be materially relieved by this new departure. At short intervals Dr. Sylvester plans to give dances, concerts, and other entertainments, in which the musical feature will be given prominence.

Obituary.—William C. Benedict, M.D., a retired senior practitioner of Brooklyn, died August 17th, aged seventy-six years. At the time of his demise he was spending the summer at Pine Hill, New York. The cause of his death is assigned to have been due to heart failure, brought on by the intense heat of the previous week. He was born in Schenectady in April, 1820. He graduated from Union College in 1840, and then from the University of Pennsylvania. After his graduation he became connected with the Blockley Hospital for the Insane in Philadelphia, where he rose to the position of chief physician, and remained two years. He then became one of the managers of the insane asylum at Poughkeepsie, N. Y., which place he filled for about a year. In 1844 Dr. Benedict moved to Brooklyn and became prominent during the cholera plague. He is said to have treated the first cholera victim, and was successful in saving his patient's life. Dr. Benedict is survived by two sons and two daughters. His wife died in 1894.—Jerome Cochran, M.D., University of Nashville, and Vanderbilt University Medical Department, Nashville, Tenn., class of '61, died in Montgomery, Ala., August 18th, from chronic nephritis. He was a member of the American Medical Association, State Health Officer of Alabama, as well as a member of the following organizations: American Public Health Association, Alabama Medical Association, and State Board of Medical Examiners. Dr. Cochran was one of the foremost sanitarians in the medical profession, and was the instigator and promoter of all the recent sanitary enactments of the legislature of his State. He was also an ardent advocate of a National Health Bureau. He was a recognized authority on yellow fever, and wrote exhaustively upon that subject.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.

Sixty-fourth Annual Meeting, held in Carlisle, England, July 28, 29, 30, 31, 1896

(Continued.)

SECTION ON OBSTETRICS AND GYNECOLOGY.

On Thursday, July 30th, DR. AMAND ROUTH opened the discussion on

SECONDARY PUERPERAL HEMORRHAGE,

which he defined as that which occurred after the doctor had left the house and after firm uterine contractions had once occurred. Whether concealed or external, he regarded retained portions of placenta or membranes as the most frequent cause, although it might occur from inertia or detachment of thrombi. Other speakers suggested as possible causes bleeders, intrauterine fibroids and distended bladder. The treatment suggested was emptying the uterus, bimanual compression supplemented by hot douches, and the hypodermic injection of ergotin. Dr. Donald said that he had seen several cases of free uterine bleeding with toxic symptoms about the ninth day, from overfeeding and constipation. For these he recommended purgation. Intravenous injections of saline solutions were suggested for cases of exsanguination. Compression of the abdominal aorta is sometimes advisable. The importance of curettage was also mentioned.

DR. BERRY HART read an interesting paper upon

THE SYMPTOMS AND NATURE OF THE SO-CALLED FLESHY MOLE,

which was illustrated by diagrams and specimens. Dr. Fothergill remarked that the terms "blighted ovum" and "fleshy mole" might be applied to two varieties of missed abortion, but in the latter the effusion of blood, which was absent or unimportant in the former formed a clot and was gradually organized. Dr. Cameron showed a preparation of the fleshy mole with an early embryo, and indulged in some remarks upon the medico-legal aspects.

DR. JOHN D. WILLIAMS presented a paper on

ANTI-STREPTOCOCCIC SERUM IN THE TREATMENT OF THE PUERPERAL SEPTICEMIA.

In the cases reported it gave unsatisfactory results.

On Friday, the 31st, the subject for discussion, presented by DR. MILNE MURRAY, was

THE RELATIVE ADVANTAGES OF FORCEPS AND VERSION AS A MEANS OF EXTRACTION IN CASES OF MODERATE PELVIC CONTRACTION.

In illustrating the methods of instrumentation, Dr. Cameron showed Smellie's first pair of wooden forceps. Dr. Murray's advocacy of axis-traction was generally commended by the several speakers.

DR. CHRISTOPHER MARTIN then read a paper on

HEMATOMETRA AND PYOMETRA,

based upon six cases. He stated that he had never met a case of hydrometra, but that accumulation of blood or pus in the womb was rare, dangerous, and difficult.

Dr. Cameron presented a paper on retroversion of the gravid uterus, with a new method of treatment, and Dr. Fothergill read a paper on Walcher's position, in which he recalled the fact that years ago Matthews Duncan had described and figured the nutation of the sacrum.

SECTION ON PATHOLOGY AND BACTERIOLOGY.

On Thursday the proceedings opened with a paper by DR. J. S. HALDANE upon

COAL-GAS POISONING.

In recent investigations he discovered that carbon monoxid was not a protoplasmic poison, like carbon

dioxid, but acted simply by preventing oxygen from combining with hemoglobin. He said that a great public danger was developing in the tendency of gas companies to adulterate their coal-gas with water-gas. The supply now often contained from eighteen to twenty per cent. of the latter instead of five or six per cent.

Dr. Alexander Scott spoke of the effect of the "clear gas" found in ammonia factories, which consists of the two oxids of carbon, in its effect upon the nervous system. Dr. Haldane, in further discussion, stated that it was useless to give oxygen to patients when more than an hour had elapsed after exposure to the gas.

Professor Fraser's paper on

THE LIMITATIONS OF THE ANTIDOTAL POWER OF ANTITOXINS

was next read, though the author was not present. He gave an account of his methods of standardizing antivenene, and gave as his opinion that the reaction of this substance was due to the formation of a chemical antitoxic product in the blood. With this view Professor Calmette differed, and thought it due to the susceptibility of the protoplasm of animals to the toxins of venom.

Dr. Risien Russell followed with a contribution to our knowledge of afferent and efferent tracts in the cerebellum, in which some facts relating to the influence of that organ upon the cerebrum were extremely well brought out.

On Friday the discussion was less active. The first subject presented was

THE RELATION OF THE MORBID CONDITIONS ASSOCIATED WITH THE PRESENCE OF STREPTOCOCCI.

Dr. Woodhead spoke of the great prevalence of microörganisms in explaining the vast number of diseases caused by them. Six varieties of streptococci were recognized from the difference of their products, their structure and appearance being the same. He spoke of the virulence of cultivated cocci produced by Marmorek's method, and suggested that the varying conditions of the tissues might account for the difference in virulence developed from the same organism in different cases. He said that each streptococcus is capable of existing in two forms—first as a saprophyte, when all of its energies are devoted to the production of its kind, and secondly as a parasite, when it is fighting for its own existence. It is in this latter phase that toxins are elaborated. Dr. Muir suggested that the only real test of the identity of two microörganisms was to immunize with one and observe if injection of the other was ineffectual.

Section of Ophthalmology.

This Section was introduced on Wednesday, July 29th, by an address from the president.

THE PATHOLOGICAL ANATOMY OF VARIOUS TISSUE CHANGES AT THE MACULA LUTEA, AND OF CERTAIN FORMS OF KERATITIS

was presented by Professor Nuel of Liege. This was a most important contribution, and in his microscopic demonstrations of albuminuric retinitis, glaucoma, and detachment of the retina, marked changes were shown in the layer of Henle. In some cases the edema of this layer was limited to the macula. He further showed that in toxic amblyopias, contrary to the common opinion, the primary change was in the macula, and the nerve changes were in the nature of ascending degeneration. The view that this condition is due to a retrobulbar neuritis must, therefore, now be given up. The specimens relating to forms of keratitis were not wanting in interest.

The paper upon

THE PATHOLOGY AND BACTERIOLOGY OF PURULENT KERATITIS,

by Professor Uhthoff and Dr. Axenfeldt, was presented, in which they regarded *ulcus serpens* as due to an infection of Fraenkel's pneumococcus.

Dr. Cecil Shaw read a paper recounting

EXPERIMENTS MADE UPON THE CORTEX OF THE OCCIPITAL LOBES IN MONKEYS.

Hemiopia was noted in all cases.

THE OPERATIVE TREATMENT OF HIGH MYOPIA

was presented by Mr. Lawford, who stated that eyes with less than 11 D. or 12 D. of myopia were unsuitable cases for operation, and the use of this method should be governed, in a large degree, by the health, social environment, and duties of each patient, as well as the condition of the eye itself. Van Hippell had reported cases of successful operation upon eyes presenting 35 D. to 50 D., and it might, therefore, be concluded that there was no limit to the degree of error suitable for this method, provided the condition of the eye itself was favorable. In the lens extraction he had abandoned the preliminary iridectomy as the circular pupil was more important in these cases than in those of senile cataract. Only four out of sixty-eight cases operated upon gave an unfavorable result. Mr. Cross regarded detachment of the retina as due to senile changes rather than myopia, and related his experience with the operative treatment of the latter. Mr. Percival demonstrated by optical formulæ that in aphakia the posterior pole of the eye should be situated 31.1 mm. behind the cornea in order that the eye should be emmetropic. In closing this discussion Mr. Lawford presented the question as to whether a child of ten years of age with 8 D. or 9 D. of progressive myopia should be operated upon, or should wait for further development of the error, the unfavorable pathological changes continuing meanwhile.

On Thursday, Dr. Maxwell of Dublin, presented a paper based on one hundred and sixty-eight cases of

CONVERGENT SQUINT,

in which he discussed precision in squint operations. Seventy-one per cent. of these cases occurred before the age of three years, and the average refraction of each eye was + 3 D. The average degree of squint measured in angles by the perimeter was 30°. In fifty-seven cases a simple tenotomy was performed, which reduced the squint on the second or fourth day after the operation by 17.5°. When again tested, on the fourteenth day afterward, the reduction was found to be about 15°. When the sound eye was subsequently tenotomized, the final retraction was found to be greater than the primary. He then described a new method of operating for which a special

instrument was necessary, which showed on a scale how much the tendon was raised from the globe, and was intended to indicate, during the operation, how great a shortening might be anticipated. The amount of squint that an eye should have when entirely due to hypometropia was 3° for each diopter. Professor Landolt pointed out that squint depended essentially upon the innervation from the convergence-center, and not upon an anomaly of the converging muscles, and said that the credit for cure was rather to be attributed to the *vis medicatrix naturæ*, than to the surgeon who set back a muscle a definite number of millimeters. The object of the surgeon should be to strengthen the weak muscles rather than to weaken the strong. An advancement operation, therefore, is preferable to a tenotomy. In closing, Dr. Maxwell said that he allowed 5° of squint to remain when operating.

SNELLEN'S OPERATION FOR EXTRACTION OF SENILE CATARACT

was then discussed in a paper by DR. BERRY. The special feature of the operation was an incision occupying half the corneal margin with a large conjunctival flap. He recommended the operation strongly, stating that the anterior chamber was usually reformed in an hour or two, and that prolapse of the iris did not occur except occasionally during the operation, when it was easily replaced. Mr. Cross of Bristol, thought healing took place more readily when the conjunctival flap was made, but found the hemorrhage sometimes troublesome.

Evisceration was advocated by Mr. Bickerton.

MR. LAWFORD read a paper upon

THE FORMATION OF AN ARTIFICIAL PUPIL BY EXTRA-OCULAR IRIDOTOMY,

an operation devised by Schöler.

THE CURE OF OBSTRUCTION OF THE NASAL DUCT

was discussed by MR. BICKERTON, who advocated the use of hollow silver stiles, which were suggested by Dr. Fox of Philadelphia. These might be worn for years without discomfort.

On Friday DR. MAXWELL read a paper treating of the

EFFECTS OF NASAL OBSTRUCTION ON ACCOMMODATION.

He gave details of five cases in which cure of accommodative asthenopia followed treatment directed to the nasal passages alone. He thought the condition was brought about by reflex nervous influences traveling through the fifth and long ciliary nerves. Dr. Batten discussed the relationship between the two conditions, which he had frequently observed.

DR. EDGAR STEVENSON presented a paper upon

THE TREATMENT OF CORNEAL OPACITIES BY ELECTROLYSIS.

He used a current of ¼ to ½ milliampere and a pressure of 3 volts. The anode was placed on the cheek of the opposite side, and the cathode, consisting of a smooth silver probe, was applied to the corneal opacity and gently moved over the surface. An amperemeter and rheostat should always be used, and great care exercised that the current does not exceed ½ milliampere. Cases illustrating the success of this method were presented. Not more than fifteen consecutive applications should be made, as there was danger of softening the cornea.

DISEASES OF CHILDREN.

The first subject discussed was

THE ELEMENTS OF SUCCESS AND FAILURE IN TRACHEOTOMY IN CHILDREN,

by DR. CAMERON. One of the first elements upon which success might be based was that of late operation, in his estimation, because in the latter stages there was less danger of wound infection, and the case was more nearly convalescent when the operation was done. By strict conformity to the middle line, bleeding was more readily avoided, and a clear view of the tracheal rings should be gained before opening the wind-pipe. The speaker had observed two cases of prolapse of the thymus gland into the lower angle of the wound. Mr. Tubby suggested that age was an important factor in the success or failure of tracheotomy, a patient under one year of age seldom recovering, and the prospect of success rising with every year of the child's life. He regarded it as important that the head and neck be kept in a straight line, and that the retractors be assigned to one person only. The tube should be permanently out of the throat by the fourth day at the latest. He also advocated the removal of the silver tube after the first day, and replacing it by a rubber one, which should be worn only a few days. Dr. Simpson was interested in Dr. Cameron's suggestion of late operations. Dr. Renton expressed a highly favorable opinion of intubation, which he had practised with success. The steam-kettle was condemned as reducing the vitality of the child.

DR. HUNTER MACKENZIE presented a paper on

PAPILLOMA OF THE LARYNX IN CHILDREN.

On Thursday, July 30th,

SPORADIC CRETINISM

was introduced as the subject for discussion, in which DR. PARKER first took part, and exhibited the photographs of forty-eight cretins which he had collected. Dr. Thomson of Edinburgh, demonstrated by photographs great improvement from the thyroid treatment in children, less in adults. Mr. Victor Horsley showed a slide illustrating a case of intrauterine rickets in a case of cretin. Dr. Beach spoke of the causation, a neurotic inheritance being a chief factor. As to sex, in a collection of cases made by him, forty-three were males, and seventy-three females, which contrasted with the relative frequency of occurrence of myxedema. In sixteen cases examined *post-mortem*, there was absence of the thyroid. Dr. Thomson further mentioned that his cases, treated by the fresh gland, did better than those treated by the tabloids.

On Friday, Dr. JOHNSTONE CAMPBELL presented a paper entitled

THE ADVANTAGES AND DISADVANTAGES OF USING STERILIZED MILK.

Heat he considered the only safe treatment to render milk germ-free. The advantages of raw milk were that the fats were more digestible, the salts more assimilable,

and the casein more digestible, and the taste nicer. The disadvantages were the risks of contamination with germs of disease. To prevent the latter, he gave extended directions as to the care of cows and the dairy in general. Dr. Coley regarded the tubercle bacillus the first and greatest menace in the use of raw milk. Dr. Carmichael considered that they were far behind Continental and American methods, and hoped the discussion would pave the way for a more active public knowledge of this subject, and the provision of centers where sterilized milk could be procured. He regarded Pasteurization of milk as sufficient for all ordinary purposes. Dr. Church urged that milk sugar should be the only sugar added to milk, as it was better for the child.

BACTERIOLOGY OF INFANTILE DIARRHEA,

was the subject of a paper presented by Dr. Macfayden, and

IMPERFORATE RECTUM,

was discussed by Drs. Ross and Simpson.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, June 15, 1896.

The President, Joseph E. Janvrin, M.D., in the chair.

J. Lewis Smith, M.D., read a paper entitled

REMARKS ON NASO-PHARYNGEAL INFLAMMATION.

(See page 225.)

DISCUSSION.

Dr. Francis J. Quinlan said that in all cases of nasopharyngeal inflammation it was important to determine by a careful local examination the parts which were affected by the disease. It was well, therefore, to explore the entire length of the nasopharyngeal tract. It was a fact that many of the cases of more or less chronic diseases were due to nasal stenoses of one variety or another. To determine the exact location of the stenosis required a careful exploration, and for this purpose it was generally necessary to make a preliminary application of cocain to the mucous membrane. Sometimes we found cartilaginous hypertrophy, sometimes polypous growths, and sometimes various other conditions giving rise to stenosis.

The nose had four functions to perform: (1) to purify and filter the air inhaled; (2) to saturate the air with moisture; (3) to warm the air; and, (4) to act as the organ of smell. It could be seen, therefore, that the nose had a very important part to perform in rendering the air inhaled of a suitable condition to be taken into the lungs. If there was any obstruction in the nasal tract the air inhaled was taken in through the mouth, and the most serious consequences were liable to result.

If there was no obstruction of the nose itself there might be some interference in the naso-pharyngeal space. One of the most frequent of these was a chain of masses of adenoid, or, more properly, lymphoid tissue, making a complete circle at the base of the tongue. By means of this obstruction the whole physiological process of breathing was converted into a pathological one.

As a result of neglect to remedy this condition we saw numberless children with open mouths and expressionless countenances, whose mental development was seriously interfered with. Such children always slept badly and were liable to attacks of croup, to nocturnal enuresis, to diarrhea, and various digestive disorders, and to a large number of neurotic conditions, including chorea. The nose was the gateway to the lungs, and if it did not properly fulfil its functions the individual must inevitably suffer. If it were asked why a child with such obstruction should have attacks of croup, etc., at night, and not in the daytime, the answer was because at night the nares were more constricted. The blood vessels were interfered with, there was pressure at the base of the brain, and the sphincters were relaxed.

As a rule, children with this adenoid obstruction bolted their food. In consequence, the process of digestion was usually interfered with, and rachitis, with its pigeon breast and long train of attendant evils, was exceedingly apt to be developed. Moreover, many of the serious conditions, which are met with in adults, were simply the results of nasopharyngeal obstruction during childhood. Of course, there might be traumatisms, but it was a fact, unfortunately, that the obstructive conditions here referred to were too frequently overlooked until almost irreparable damage had been done. In his paper, Dr. Smith had treated of diphtheria and various other acute diseases which had their primary seat in the nasopharyngeal tract. It could be readily seen that a disordered tract was only too ready to receive infections from whatever source, and that a child which did not breathe properly (whether the obstruction was due to enlarged tonsils, adenoid proliferation, or other trouble), would be much more liable to contract such acute diseases than one whose respiratory apparatus was in a normal physiological condition. He had no doubt also that the various forms of malignant disease are more easily contracted by individuals whose nasopharyngeal tracts were diseased.

Dr. J. R. MacGregor said that his own observations corroborated the experience of Dr. Quinlan, and he had only one or two reflections to present the effect of acute inflammations, as represented by diphtheria, influenza, etc., on the nasopharyngeal passages was of more importance, he believed, than was generally supposed to be the case. Having personally gone through several attacks of influenza (one of them last autumn), he appreciated very thoroughly the peculiarly irritating character of the mucous and muco-purulent discharges which were so distressing to the patient suffering from that disease. His own experience led him to substantiate the statements of Dr. Smith as to the importance of thoroughly cleansing and disinfecting the cavities in these acute disorders. Another fact which he had observed was that they led to a peculiar form of rhinitis, which is liable to become chronic, and in children, especially, to atrophic rhinitis. At the Metropolitan Throat Hospital, with which he was connected, he had been surprised at the comparatively large number of children, of eight or nine years of age (sometimes even of only six), who suffered from atrophic rhinitis. The importance of being alive to the liability of this danger, seemed to him to be very great. If proper treatment were commenced early enough, many could,

no doubt, be saved from ozena. It had formerly been supposed that atrophic rhinitis followed in the wake of hypertrophic rhinitis, but this was certainly not the case, especially in the young.

Another speaker said that the statements made by Dr. Quinlan seemed to him to be somewhat confusing. The doctor had attributed all sorts of disorders to adenoid disease, but his opinion was that, while undoubtedly it did sometimes cause these reflex troubles, it was only one of a variety of causes. When, therefore, we operated for the removal of this adenoid tissue, we should make it a point never to guarantee relief to our patient, since there might be some other factor at the bottom of the trouble. He then proceeded to speak of the treatment of acute nasopharyngeal catarrh, or ordinary "cold in the head." During the past winter, both in private and hospital cases, he had tried all of the various remedies, which have been lauded in this condition, and he had found that, one by one, they had failed in the test. Among the agents which he had employed were quinin, tartar emetic, squill, antiseptic douches, eucalyptus, menthol, etc. Only a few patients who were the subjects of cardiac disease and were resting in bed got well in a marvelously short time. This result, he thought, could be attributed only to complete rest in bed and to massage, which was practised three times a day. In addition, the room occupied was kept at an even temperature. All these patients recovered from their catarrh within about forty-eight hours.

If the patient could not, or would not, rest in bed, local treatment might be resorted to, but it did not seem to make much difference what agent we used in the nasal douche. Salt and hot water, borax, boracic acid, or salicylate of soda, in the proportion of a dram to the pint, would do as well as anything else. The patient should always be carefully warned against allowing any of the fluid to get into the Eustachian tube. To avoid this, the vessel containing the solution used should not be held higher than six inches above the nose, the head should be held forward, with the mouth open, and the patient should resist the first tendency to swallow the liquid. It would be found that the frequent removal of the discharges would afford a great deal of relief. Sometimes when the nares were very much obstructed, it was desirable to inject into them a one per cent. solution of cocain at the commencement of the treatment, but this should always be done by the physician himself. Later, such agents as menthol, benzol, etc., might be resorted to with more or less benefit. General treatment was unimportant, except in cases not treated by rest at the outside. The most important class of remedies were tonics, such as cod-liver oil, malt extracts, etc.

Dr. Smith, in closing the discussion, said his chief object in writing the paper, which he had read, was to elicit the opinions of specialists upon the importance of nasopharyngeal inflammations which the general practitioner often overlooks or considers secondary. What he had heard had confirmed him in his opinion in regard to their importance and the necessity of local measures either alone or in conjunction with constitutional treatment.

At the social reunion after the meeting, which was the last one of the Association before the summer vacation, remarks were made by ex-Presidents John Shrady, S. B. W. McLeod, J. R. MacGregor, and George T. Harrison.

CORRESPONDENCE.

THE MEDICAL NEWS AND QUACKERY.

To the Editor of THE MEDICAL NEWS:

DEAR DOCTOR: It is a pleasure to express my thanks and gratitude for the vigorous opposition you have made to the experiment of treating inebriety by secret drugs at Bellevue Hospital. A similar criticism and denunciation of gold-cure specifics by two London journals broke up a great charlatan scheme, and received the warmest praise and endorsement of the British medical public. An independent medical press, not afraid to expose frauds and defend common-sense views of practical medicine, is always welcomed by the profession. The NEWS, by its just criticism of this matter, has won an enviable place in medical journalism, which, I am sure, will be remembered for a long time to come.

Again thanking you, believe me

Yours truly,

T. D. CROTHERS, M.D,

HARTFORD, CONN.,
August 22, 1896.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE 16 DAYS ENDED JULY 31, 1896.

CARTER, H. R., Surgeon, directed to inspect Marine Hospital at Tampa, Fla., July 28, 1896.

PECKHAM, C. T., Passed Assistant Surgeon, directed to report to Surgeon Godfrey, Chairman of Board for Physical Examination, July 24, 1896.

BROWN, B. W., Passed Assistant Surgeon, granted leave of absence for six days, July 23, 1896.

STEWART, W. J. S., Passed Assistant Surgeon, granted leave of absence for four days, July 17, 1896.

DECKER, C. E., Assistant Surgeon, to proceed from Battle Creek, Mich., to St. Louis, Mo., for duty, July 21, 1896.

PROCHAZKA, EMIL, Assistant Surgeon, granted leave of absence for twenty days, July 23, 1896.

BOARD CONVENED.

Board convened to meet at Port Townsend, Wash., for the physical examination of Passed Assistant Surgeon C. T. Peckham, Surgeon John Godfrey, Chairman; W. G. Stimpson, Recorder, July 24, 1896.

PROMOTION.

BANKS, C. E., Passed Assistant Surgeon, commissioned as Surgeon, July 27, 1896.

DEATH.

FESSENDEN, C. S. D., Surgeon, died at Salem, Mass., July 23, 1896.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 28, 1896, TO AUGUST 3, 1896.

The leave of absence, on account of sickness, granted Major James C. Worthington, surgeon, is further extended one month, on account of sickness.

Leave of absence for one month, to take effect on or about August 5, 1896, is granted Major Henry McElderry, surgeon, Fort Robinson, Neb.

ORIGINAL ARTICLES.

HOW CAN SUPPURATION BE BEST PREVENTED IN ACUTE PELVIC INFLAMMATIONS?[1]

BY WM. R. PRYOR, M.D.,

OF NEW YORK;

PROFESSOR OF GYNECOLOGY IN THE NEW YORK POLYCLINIC, CONSULTING GYNECOLOGIST TO THE CITY HOSPITAL.

I SHALL not treat of those forms of pelvic inflammation which arise from disease of the pelvic bones, from bowel disease, or from other causes which are operative in men as well as women; but shall confine myself strictly to those inflammatory conditions which arise from causes extending through the uterus.

In the earlier application of laparotomy to the treatment of inflammatory diseases of the uterine adnexa, conditions were met with which could only be treated by removal of the affected parts. The subjective symptoms were of the most distressing nature, and examination demonstrated an extensive involvement of the pelvic peritoneum, together with ovarian and Fallopian disease. Having obtained marked success in removing the grosser evidences of chronic pelvic inflammation, as pyosalpinx, hydrosalpinx, etc., we began to apply the radical operation of laparotomy to the treatment of the more acute forms of tubo-ovarian disease. Just here we made a mistake.

I had met with a number of cases of gonorrheal infection of the uterus and tubes in which nature apparently affected a cure; certainly, disagreeable symptoms disappeared, and examination showed no marked pelvic lesions. Applying to a consideration of these inflammations observation made in the study of the extension of infection in other parts of the body I began to seek for some means to assist in the cure of these cases. The idea struck me that I might here apply the surgical rule that stopping the supply of infectious material conduces to a cure of its complication and prevention of extension; and in 1891 I began to curette the uterus for acute salpingitis and peritonitis. The results obtained were startling. A riper experience and more careful observation of my cases have led me to expect a cure (or rather, to retain the idea of my paper, to prevent suppuration) from curettage, irrigation, and the use of antisepsic dressings in one class of cases only, namely, those cases of first infection when seen within a week after extension of the infection outside the uterus. This operation, the advocacy of which brought so much unpleasant criticism upon me, is now the accepted routine procedure in most of our general hospitals.

I have applied it in nearly a hundred cases of acute first attacks and have never seen failure result from it when early applied. If we secure good results from this treatment, where an infection has already extended to the tubes and pelvic peritoneum, it may be presumed that the curettage is indicated whenever the endometrium is infected. My experience has taught me that such is the case. The causes of failure in the hands of others I have traced to the use of strong antiseptics within the uterine cavity, partial removal of *débris*, and incomplete packing of the uterus.

The observation and experience of six years with conservative curettage have taught me to surely expect a complete recovery in cases of acute endometritis with salpingitis and peritonitis when seen early in first attacks.

I do not divide the cases according to the infection, whether septic or specific, but treat all pyogenic infections alike. But there are many cases which are seen late; there are other cases which present an acute process implanted upon a chronic, cases of chronic relapsing salpingitis; and still other cases which have been cured entirely, so far as we can see, by operation years before, but have become reinfected. Although these cases are certainly most acute, it must not be forgotten that previous attacks of tubal and peritonitic inflammation have markedly changed the nutrition of the affected organs.

Suppuration *may* not ensue, but it is likely to. Curettage helps all these cases somewhat, but so many failures to afford entire relief result where curettage alone is employed that more must be done. Henrotin, Chicago, has written very ably upon this subject, and credit for the idea is due him. For two years, in all such cases, I have operated as follows: The uterus is thoroughly curetted and irrigated. All instruments being changed, in a few minutes, the cul-de-sac is opened and a wide blunt dissection made in the vagina

[1] Read by title at the Twelfth Annual Meeting of the Fifth District Branch of New York State Medical Association, held in Brooklyn on May 26, 1896.

and cul-de-sac by separating two fingers. The fimbriated ends of the tubes are opened if found closed. All serous-fluid accumulations are evacuated, and the pelvis wiped dry. No irrigation is here used. I then pack from three to five yards of iodoform gauze into the pelvis, each strip being about three inches wide. The uterus is next tightly packed as is also the vagina. A self-retaining catheter is introduced. On the third day the vaginal gauze is removed, together with that in the uterus. The vaginal gauze is renewed but the uterine packing is not, unless the uterus be large. The gauze in the pelvis comes out in a week or ten days under chloroform and another large pelvic packing is made.

The results of this operation are most gratifying. The lymph which is thrown about the antiseptic dressing disappears in a few months and the uterus becomes perfectly movable. Accidents have never happened to me and I have so far been uniformly successful in preventing suppuration. In several of these cases of relapsing salpingitis I have met with large hydrosalpinx and broad ligament cysts. These were merely incised and evacuated.

So much has of late years been written upon hysterectomy in inflammatory cases that the profession at large has come to believe pretty generally that we gynecologists have nothing else to offer a woman who has pelvic peritonitis other than some mutilating operation. These two operations, one matured, the other new but sufficiently tried, will very effectually prevent suppuration in the pelvis when properly applied. All the criticism which has been put upon the operation of hysterectomy is not merited, but most of it is. He who first sees these cases of pelvic inflammation, folds his hands, orders opium and poultices, and lets the infection run riot in the woman's pelvis, is the man to blame. I consider it an imperative duty to treat pyogenic infection here by surgical means only. Laparotomy is no longer warranted, unless there be pus present, for peritonitis of a distinctly pelvic character. We have in these two operations the means to prevent the wholesale mutilations which we see advertised on every college and hospital bulletin board. But we must get our cases early. The responsibility resting upon the family physician is great. I state it as mildly as I can when I say that the greatest nonsense ever receiving the support of intelligent men was Alonzo Clark's treatment of peritonitis by opium. Pelvic inflammation is due to an invasion from without. One very common result of such infection is production of pus. Nowhere else in the body will the surgeon adopt the stasis plan of treatment of an infection. Incision into the cul-de-sac immediately relieves these women of pain. Very often within twelve hours the bed is soaked with serum, so great is the drainage. The breaking up of adherent lymph-plates opens the mouths of the infection-laden lymph-streams and they pour all their contents into the gauze. These operations take the place of opium and poultices; they do not, by locking up the emunctories, foster infection, but stop it short. I feel that I have something between the poultice or ice-bag and the horrible hysterectomy. I believe I can nearly always prevent suppuration.

I cannot too strongly urge you to apply to the acutely inflamed pelvis of a woman those general surgical principles which are embodied in the two procedures of (*a*) cutting off the primary source of an infection, and (*b*) draining away its results. This is the truest conservatism, for it seeks the conservation of tissue diseased and, at the same time, protects the general economy against the results of diseased processes. Above all, it leaves the woman her menstrual function. These women are symptomatically and physiologically cured, for they bear babies afterward.

In reviewing my experience of the last sixteen years, I believe I can at last see my way to prevent the formation of pus where the tubes and peritoneum are involved; and I feel much gratified upon being able to present these operations to you. For many months, week after week, I have shown these operations to the practitioners who honor me with their presence at my lectures. I have hammered at them with the irresistible arguments, demonstration and result. From among the seven or eight hundred who have gone out, some have tried the cul-de-sac opening where before they used opium. Their letters are indorsement enough. I shall be more than repaid if I can make among you a few converts.

DISCUSSION.

Dr. James H. Etheridge of Chicago, considers that Pryor's operation, as this surgical operation will be designated in the future, has come to stay. It offers the only solution of a most serious gynecological problem. When a woman is infected with gonococci she is almost certain to develop a specific perimetritis before she is freed from this loathsome malady, with its resultant sufferings, adhesions, tubal and ovarian distortions, and hopeless sterility. Thousands of young men acquire gonorrhea, and before marrying their innocent

sweethearts find it agreeable to their convictions of propriety to get rid of the disgraceful disease, as they think they can easily do. Within a few weeks after marriage the poor wives acquire urethritis, cystitis, vaginitis, endometritis, salpingitis, perimetritis, sterility, and broken hearts. The part that has been played by the medical profession has been almost complete inanity in the presence of the wickedly energetic, aggressive gonococcus, whose onward march has not been interrupted one moment. His ravages are checked only when nature throws out a wall of protecting lymph beyond his line of march well up in the pelvis, by which he is permanently picketed from future destructive conquests and compelled to lay down his arms and perish from starvation, after having wrecked the poor woman's life for an indefinite period of time.

Dr. Pryor has exhibited great wisdom in studying carefully the habits of the gonococcus and in presenting to the medical profession a simple, safe, and efficient method of circumventing its method of warfare on helpless women. He goes in above and beyond the progress of this microörganism, and completely and effectively cures this disease in woman for the first time in the history of medicine. Thousands of women who have had gonorrhea are alleged to be cured, but gynecological operators who, later, remove a pyosalpinx from one or both sides, know that they were *not* cured at all. I firmly believe that we rarely *cure* a gonorrhea in women by any of the recommended lines of treatment to-day. Having run the entire gamut of such lines of treatment and found them all sadly deficient in effectiveness, I can but welcome Dr. Pryor's brilliant conception with warmest plaudits, and assure him that he is the author of a means of saving many a woman's life from suffering and a wrecked future.

SERIOUS HEART LESIONS WITHOUT WELL-MARKED CONTINUOUS PHYSICAL SIGNS.

By HENRY L. ELSNER, M.D.,
OF SYRACUSE, N. Y.;
PROFESSOR OF THE SCIENCE AND ART OF MEDICINE AND CLINICAL MEDICINE, SYRACUSE MEDICAL COLLEGE.

THE clinician who depends entirely upon continuous physical signs for the recognition of all cardiac lesions will be likely to overlook numerous cases in which a thorough appreciation and interpretation of subjective symptoms, with occasional and transitory objective manifestations, would lead to a correct conclusion.

There are conditions more important in cardiac diagnosis than the simple recognition of incompetent and stenosed valves, though many of our text-books have not succeeded in making that fact clear to the profession. Experience has demonstrated the great importance to the diagnostician of understanding the true condition of the heart-muscle and of determining with equal accuracy the degree of functional activity.

The progress made during the past few years in the treatment of heart disorders, by methods in which we are particularly interested, has caused me to bring to your notice to-day the subject of "Serious Heart Lesions Without Well-Marked Continuous Physical Signs."

I shall rehearse fully the history of a typical case and confine myself to deductions which seem to me justified after clinical observation and pathological examination of others:

G. S., of Auburn, N. Y., aged forty-six, merchant, consulted me September 16, 1891. He was well-built, well-nourished, with an unusually good muscular development, and a man of exemplary habits. He used tobacco moderately. His family history was negative. He had never been treated for constitutional syphilis, though, when a young man eighteen years of age, he said that he had a little ulcer on his penis, which healed very readily in a few weeks, after which his attending physician told him that further treatment was unnecessary. Though constitutional symptoms had never been noticed, in the light of his subsequent history I have always suspected very strongly that he had syphilis, and treated him in accordance with such suspicion. In 1888 he had a slight attack of muscular rheumatism, for which he went to Mt. Clements, where he rested a few weeks, took the baths, and returned home cured. During the eight years preceding his visit to me, he had been considerably annoyed by a sense of discomfort after eating, in the region of the heart, which followed all hearty meals. This uncomfortable sensation was later accompanied by an occasional shortness of breath, or, as he expressed himself, "superficial and unsatisfactory breathing." If he walked to his place of business after eating, a distance of one-half mile, he had noticed also that his breathing became worse —more labored—and that there was more or less numbness of the left arm, forearm and hand, while his left shoulder became painful until he rested for a few moments, when the pain and numbness completely disappeared. Later actual pain was substituted for the left-sided numbness, and at one time before I saw him he suddenly, after a moderate dinner, while walking to his store, was suddenly seized with symptoms of alarming angina. During this attack his physician, Dr. Cheesman of Auburn was called, who immediately recognized the fact that the patient was suffering from serious disease, though, on physical examination, nothing abnormal could be found. When, on September 16, 1891, Mr. S. consulted me, his appearance was that of a perfectly healthy

man. His only complaint was of the discomfort after eating and the increase of numbness and pain in the left arm during the preceding month, with an increasing sense of weight, causing a feeling of constriction in the upper thoracic regions. His breathing was becoming more and more labored whenever he made the attempt to walk after eating. His friends noticed a growing pallor during the continuance of the dyspnea and pain; at other times his color was good. As time went on, his breathing occasionally became slightly uncomfortable; if he did not walk after eating, this was not associated with numbness or pain in the left arm.

No amount of walking or exercise when the stomach was empty at this time gave rise to dyspnea or symptoms of angina. There was no headache, nor were there eye-symptoms, edema of the extremities, or puffiness of the face. There were no nervous symptoms; the patient slept well, his appetite was good, and his bowels regular. He passed the normal quantity of urine, and during my observation of him repeated examinations of it gave negative results. The anginous attacks were not followed by polyuria. Ophthalmoscopic examination was negative. Reflexes were normal. No hysterical symptoms.

Physical examination on September 16, 1891: Aside from a slight gastrectasia, there were no abnormalities present. A careful examination of the heart showed its outlines to be normal; the heart-sounds were everywhere clear and distinct. There was no broadened area of aortic dulness. The pulse was 70, of good character, with arteries of normal resistance and tone.

Directing the patient to walk uphill for ten minutes and to return for reëxamination, I found no change in the cardiac outlines; the pulse became more accelerated—90 and feeble—while the heart-sounds were less distinct than before; the aortic sounds seemed distant, indistinct, or embryonic, as Nothnagel has characterized them. There was no arhythmia, no complaint of fatigue or dyspnea. As a result of this examination and a consideration of the previous history, I diagnosed myocardial degeneration, in all probability segmentary, of specific origin, and due to arteritis involving the coronaries or their branches.

In the course of a few weeks I had abundant opportunity to observe the patient after hearty meals and to make careful physical examinations of the heart. During this time the symptoms were in no degree relieved by treatment. It was found that from the first of October to the fifteenth the left ventricle was dilated and reached 1 cm. beyond the mammary line to the left; no murmur could be detected. At times the pulse showed marked arhythmia, and the aortic sounds were distant and indistinct. Urine continued normal. Anginous symptoms were increasing on exertion, until it was determined to prescribe absolute rest for a short period in bed. After the rest, on the 6th of November, 1891, the dilatation had disappeared; heart-sounds were distinct and clear. He had no annoying symptoms during the period of his rest, however heartily he ate, and for a short time he considered himself much improved.

He soon gave attention to some of the details of his business and at once experienced a return of his annoying symptoms on exercise after eating. It became evident that any considerable and continuous business worry or exertion of any kind was associated with an increase of symptoms, and these, in turn, with an increased area of cardiac dulness or dilatation. The dyspnea and the pain in the left arm increased. About the middle of November these symptoms appeared independently of the taking of food. We then went to New York and consulted two of the leading diagnosticians of the metropolis, both of whom agreed that the disease was in all probability due to coronary disease and myocardial degeneration. A grave prognosis was given.

He decided to consult two other physicians during his stay in New York. He remained with the first of these consultants three or four weeks, after receiving the positive assurance that he had pseudo-angina, and that there was nothing organically wrong with the heart or its arteries. During this time he was treated dietetically and hydrotherapeutically. Having obtained no relief and lost forty pounds, he consulted another authority, who, after a minute examination, expressed the opinion that he had never seen angina pectoris due to coronary disease associated with myocardial degeneration in a man as young as the patient, and concluded that he had simple dilatation of the stomach, with pseudo-angina. Resorcin, bismuth, and cascara were prescribed, and the patient was sent home, to return to New York in three weeks, when it was confidently expected that he would be much relieved.

About one week later, on the 28th of March, 1892, I was hurriedly summoned to his bedside, where I met Dr. Cheesman, who told me of an alarming attack of angina pectoris, which he had had on the preceding Tuesday. We found the patient with an almost imperceptible arhythmic pulse, 120 per minute, at times more rapid, the cavities of the heart dilated in all directions, the aortic sounds imperceptible, the remaining heart-sounds embryonic and indistinct. There were no murmurs. His extremities were cold, his face was ashen-colored, lips were blue, he was anxious, and seemed to be *in extremis*. Urine was scanty—non-albuminous. He had no pain in the left arm during this attack. It did not seem to Dr. Cheesman or myself that the patient could rally from this condition, but on the following day, I believe, he went out for a ride. On the 5th of April, eight days after my visit, he had a similar attack, in which he died.

I have gone thus fully into the history of this case because of the transitory character of the physical signs (always disappearing after prolonged

rest), the unusually long period of discomfort associated with stomach symptoms following the ingestion of food, preceding the first alarming attack, and the great variety of opinions which had been given by those who were consulted. We were unfortunate in not being able to obtain a *post-mortem*. From *post-mortem* examination in similar cases, there can be little argument against the assumption that there was involvement of the coronary arteries and the heart-muscle.

One of the consultants held that angina pectoris is not likely to occur until long after middle life, and that specific arteritis was out of the question, because of the failure of all antisyphilitic treatment to influence in any way the course of the disease. While it is true that angina pectoris and myocarditis are conditions found in advanced life, it cannot be denied that these diseases, with their underlying obliterating arteritis, may exist during middle life, and clinicians have repeatedly established the truth of this assertion. The majority of such cases are, I believe, of syphilitic origin or hereditary. Our clinical experiences repeatedly show young men with arteries practically old and degenerated.

Oestreich[1] reports a case in which a young man, thirty-two years of age, who had previously enjoyed perfect health, died on the night of his wedding, with all of the symptoms of obstructed circulation and cardiac insufficiency, without symptoms of angina pectoris. The *post-mortem* showed beginning fibrosis of the ascending aorta. Upon an uneven and ulcerated sclerotic spot was found a thrombus, which closed the opening of the right coronary artery, and from the side of this thrombus a prolongation had become detached, which plugged the left coronary.

Porter[2] has shown that complete mechanical closure of the coronary arteries of dogs is always speedily followed by complete arrest of the heart-beat. This is attributed to anemia, which, in its development, must be followed ultimately by profound myocardial change.

The transitory dilatation of the ventricles it has been my experience to note in other cases, in which the dilatation followed strain in a heart already the seat of fragmentation or segmentary myocardial degeneration. In some of these there was an associated valvular lesion; in others, arterial disease. Recession of the dilatation followed rest and rational treatment. Auriculo-ventricular murmurs are occasionally heard during the period of extreme dilatation; as this disappears murmurs are much modified. Systole is stronger and compensatory changes are plainly manifest.

The persistence during so many years of the direct association of anginous symptoms with the ingestion of food and the accompanying distention of the stomach were misleading (though frequently encountered in this class of cases), and seemed to many to justify the diagnosis of pseudo-angina. This condition is rare, and such a diagnosis ought never to be made until all possibility of the existence of true angina with its positive pathogenic factor has been excluded.

Cases of alcoholic myocarditis[3] are common, but are not often recognized in their incipiency. The disease makes gradual progress, but often during the early stage a slightly increased area of cardiac dulness is found, with, as a rule, clear and normal heart-sounds and occasional arhythmia. Only rarely do we hear a faint systolic murmur. We not infrequently find these patients coming to the clinic or to the hospital with dyspnea, slight edema of the ankles, and other evidences of stasis. After a period of rest, with appropriate treatment, the symptoms of weak heart disappear, and it returns to its normal size. The successful treatment of these cases must necessarily include total abstinence from all spirits. We see fewer of these cases in this country than are found in Munich and other cities on the continent where beer is excessively used, but I have learned to recognize a variety of alcoholic myocarditis, the clinical picture of which answers very closely to that described by Bollinger[4] and others. These patients offer little resistance to acute infection, and in most cases readily succumb, especially to pneumonia and other acute respiratory diseases.

During the past few years my attention has been called to both permanent and transitory dilatation and hypertrophy of the heart following severe strain, undue muscular exertion and prolonged worry. In the majority of these cases I think the history will prove that the heart was not normal before the strain. This has been established in all of my cases in which the dilatation and hypertrophy continued permanently, unless the strain was continuous and and the patient had labored under it for a considerable period. See[5] and Rieder,[6] in support of this position, make the observation that in France the country letter-carriers who walk all day suffer no ill effects from their long-continued and, at times, laborious marches, probably because the normal heart, like other muscles, accommodates itself to the work. Rieder (*loc. cit.*) asserts that with a healthy condition of the heart it is exceptional and exceedingly rare to find cardiac insufficiency and dilatation with consecutive hypertrophy following severe bodily

exercise. Spillman,[7] Bernheim,[8] and Thurn[9] make the more positive statement that the normal heart never tires; that in those who are perfectly healthy, in spite of exhausting effort, there is no typical cardiac insufficiency.

Prolonged muscular exertion and consequent strain is, in all probability, an important predisposing factor in the causation of degenerative heart and arterial disease, and if those cases in which there are but occasional or transitory physical signs to lead us, are subjected to such insult, the symptoms soon become continuous and characteristic of myocardial fragmentation.[10]

In the first class of cases to which I wish to call your attention, for days at a time there exist with dilatation marked arhythmia, tachycardia, and alarming intermission of the pulse, with delirium cordis, dyspnea, and all of the other evidences of an organ ready to surrender with secondary involvement of lung and kidney. After persistent effort there has for a time, at least, been a return to apparent health, the heart acting normally, but little dilatation remaining. Some of these cases I have followed for many years and have battled vigorously against repeated attacks.

In the second class of cases we have, for a limited period, symptoms of failing heart-strength, as shown by increasing dyspnea on exertion. There are no cardiac murmurs in most of these cases, but persistent dilatation, with little or no hypertrophy. The pulse remains regular almost to the end, though there is marked tachycardia. The heart shows no tendency to mend. Sudden death follows, as a rule, after the acute symptoms have persisted for a few days or weeks. As the symptoms grow more alarming, we have all the evidences of portal and renal stasis. In these cases there is no preëxisting emphysema. In both varieties there was found marked myocardial change on macroscopic, and more particularly on microscopic examination.

We had, in our pathological examination, given but little study to the appearance of the auricles, the ventricles having received most of our attention. Arhythmia was considered a necessary symptom of fibroid or degenerated heart. Hampeln[11] proved that a regular pulse need not exclude the existence of advanced myocarditis. During the past two years I have seen two cases in which I had opportunity to observe the patients to the end. The first was a man, whom I left with a regular pulse, without a sign of impending danger, ten minutes before his death. The *post-mortem* revealed a thin ventricle, with partial rupture; the microscope gave evidence of advanced ventricular fibroid degeneration. The second case was one of complete rupture, with preceding transitory physical signs, in which there were microscopic evidences of degenerated ventricular walls and advanced coronary disease. The painstaking observations of Radasewsky[12] upon cases of ventricular disease, to which I have found but one American writer[13] refer, make a more exact localization of the lesion in the heart possible during the life of the patient. It must be accepted that Romberg and Krehl[14] were correct in their assumption that automatic and rhythmic action of the heart takes its origin in the muscular fibers, and not in the cardiac ganglia, and that the starting-point of the primary impulse to contraction is in the walls of the auricles, near the opening of the large veins.

Radasewsky's (*loc. cit.*) conclusions seem to prove that the marked irregularity of the heart in chronic myocarditis is due to a localized involvement of the auricles, and cannot be explained by changes found in the ventricles. Thus, the localization and the extent of tissue-change is made possible by a consideration of the character of the pulse and the behavior of the heart-muscle. The degeneration of the ventricles usually associated, as I have remarked, with a regular, but, as the process advances, an increasingly feeble pulse, gives a most unfavorable prognosis, because of the greater strain to which these are subjected.

The changed heart-muscle ofttimes presents a complication entirely independent of the accompanying valvular lesion.[15] We are then likely to have the clinical evidences of heart-fatigue with either diseased coronaries, connective-tissue overgrowth, or parenchymatous changes.

The most recent investigations,[16] bearing upon the anatomical causes of changed and faulty compensation in valvular lesions prove the direct association of these insufficiencies with changes in the heart-muscle consequent upon lesions in the coronary vessels. In those cases in which the valvular diseases of the aorta are due to fibrosis—and the majority of these are—it has been found that the branches of the coronaries, as well as the aorta itself, are the seat of periarteritis and endarteritis. In consequence of these changes, we find circumscribed degeneration of the muscular structure of the heart, even necrosis and ultimate foci of new cicatricial tissue.

With mitral lesions, which are more likely to be of inflammatory origin, the starting-point of the retrograde process is in the coronary veins. The right ventricle is unable to hypertrophy sufficiently, and its muscle is weak, without resistance. There

is obstruction, not only in the venæ cavæ in these cases, but the coronary veins are equally involved in the process; these are dilated, with thickened walls. Banti's (*loc. cit.*) suggestions are rational, and, in the light of anatomical observation and clinical experiences, justify us in considering that with faulty compensation and aortic lesions there is an "arterial," with mitral lesions, a "venous cirrhosis" of the heart. Increasing arhythmia, reduced heart-strength, and progressive ventricular dilatation are accompanied with more audible evidences of auriculo-ventricular incompetence and all of the ordinary symptoms of marked faulty compensation. This alarming condition can, in many cases, be postponed, though it cannot be indefinitely averted, by an appreciation of the existing complication. With valvular lesions, the first and slightest increase of dyspnea, associated with either persistent or transitory arhythmia, the slightest increase of physical signs after exertion, and with these symptoms an increasing area of cardiac dulness, whether permanent or transitory, must lead to the conclusion that the myocardium is becoming insufficient, undergoing, in all probability, degenerative or inflammatory change, requiring rest and active treatment.

When valvular lesions are associated with acute infectious processes, it is not at all uncommon to find clinical and pathological evidences of acute exacerbations of chronic myocarditis; indeed, in some of these cases the evidences of the acute disease of the heart-muscle overshadow entirely those of the valvular lesion.

Stokes,[17] in 1855, held that whatever the cardiac affection, the symptoms depend mainly upon the strength or weakness, the irritability or paralysis, the normal or abnormal condition of the heart-muscle.

Attention must be directed to the variability of the physical signs referable to the heart in many forms of anemia, either due to constitutional disturbances or local asphyxia from coronary disease, and the rapid disappearance of these under favorable environment and treatment.

The history of the cases of paroxysmal tachycardia in which the tachycardia is not a symptom, but is supposed to be an essential disease[18-20] is peculiar. There are sudden attacks of rapid heart-action with a small, thready, easily compressed pulse, and no previous history or physical signs of heart-disease. I have seen patients in these attacks with the pulse reaching far beyond two hundred per minute, at the same time found it regular, with diffuse, but feeble cardiac impulse, and ultimately, after repeated attacks, there was increase of cardiac dulness, due to dilatation, which disappeared with the disappearance of the symptoms.[18]

Dilatation is not a necessary accompaniment of paroxysmal tachycardia,[19] and when it follows is of secondary origin. Bouveret[20] mentions cases without dilatation, while Fritz[22] observed two patients during a period of three years before it occurred. Quincke and Hochhans[23] have had similar experiences. These cases of paroxysmal tachycardia must not be confounded with hysterical palpitation.

Finally, it may be positively asserted that murmurs have been heard occasionally when no organic change was found after death. It can be as confidently stated that organic change was often present when no murmur was audible. Such a case I recently saw, in which there was ulcerative endocarditis. Murmurs disappear for a time, as Fothergill[24] says, "in a perplexing manner." The aortic regurgitant, even, has been absent for distinct periods.[25] Mitral regurgitant murmurs have vanished in cases where the dilated left ventricle has been relieved, and the curtains of the valve consequently become sufficient to close the ostium.

A BRIEF CONSIDERATION OF PSYCHICAL EPILEPSY.[1]

BY ALBERT WARREN FERRIS, M.D.,
OF NEW YORK;
ASSISTANT IN NEUROLOGY, VANDERBILT CLINIC, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; MEMBER OF THE NEW YORK NEUROGICAL SOCIETY.

EPILEPSY still defies the pathologist and baffles the clinician. Although studied and treated since the time of Galen, yet in these days of exact histological knowledge and specialized therapeusis no palpable lesion is discoverable to which the epileptic neurosis is due, and no treatment is known which can be called curative. It still claims as its victims two out of every one thousand persons.[2]

The definition of epilepsy has felt the influence of evolution. It is no longer simply the "falling sickness." Scientific observation has caused a considerable modification of the easy dictum of quaint William Buchan,[3] who wrote, seventy-five years ago, "the epilepsy is a sudden deprivation of all the senses, wherein the patient falls suddenly down, and is affected with violent convulsive motions." Nor does Hughling-Jackson's latter-day definition[4] prove altogether satisfying, namely: "A sudden, rapid, occasional, and local discharge of cerebral cortex."

The theory of arterial spasm, causing local cerebral anemia, is plausible, and, if we accept it, an explanation of the syndrome of any form of epilepsy is easily elaborated. Spitzka,[5] claiming that arterial spasm accompanies the fit, defines epilepsy as "a diseased state of the encephalon, without a palpable characteristic lesion, manifesting itself in explosive activity of an unduly irritable vasomotor center, leading to complete or partial loss of consciousness, which may be preceded or followed by various phenomena, expressing the undue preponderance of some, and the suspended inhibitory influence of other cerebral districts."

Nothnagel[6] places the convulsion-center between the lower portion of the pons and the upper portion of the oblongata. He has shown that epileptiform convulsions with automatism are produced by a slight puncture at this point. If we prolong sensory irritation of a given spinal nucleus after reflex movements have taken place, the subsequent reaction (if there is any reaction beyond the plane of the segment in which the given nucleus is situated) will be in the oblongata in the form of laughing, crying, deglutition, and spasms. Irritation of certain parts of the cerebral cortex causes active anemia of certain parts of the brain, independently of the condition of the rest of the body,[1] for the cortex has the capacity of acting as a vasomotor center for the blood-vessels of the brain. A complemental hyperemia of other parts of the brain ensues, the convulsion-center is overwhelmed with the increased blood-supply, and functional excess results in the form of convulsions. The afflux of blood into special parts of the brain, through unaffected arteries, results in exalted function of the well-nourished areas. Hence the auræ, varying with the area: odors, colors, tinnitus, etc.

In *petit mal* the thalamus ganglia are probably undisturbed, and the initial arterial spasm is confined to the surface of the hemispheres. Transitory unconsciousness or abolition of cortical function occurs, without further disturbance of the patient, as his automatic ganglia carry on their functions. The less the arterial spasms the less the fall of manometrical pressure within the cranial cavity, and the less the complementary hyperemia of the lower centers. Such is the theory of arterial spasm advanced by Kussmaul and Tenner, and accepted by some neurologists.

Gowers[2] rejects the theory of arterial spasms. He refers to the fact that the experiments of Ferrier, Luciani, Bartholow, and Horseley teach that irritation of the cortex may cause convulsions. He concludes from the study of auræ that the cortex of the cerebral hemispheres is the seat of primary discharge. A case of his own and a similar case of Oebeke's confirm this view, for in each of these cases a lesion in the internal capsule occurred in an epileptic. After this accident the fits, previously general, almost ceased on the paralyzed side. The inference must be that the discharge causing the general convulsions occurred above the internal capsule, namely, in the cortex. It is unnecessary that there should be any primary change in the energy-producing action of the cortical cells; there is simply, according to this view, an instability of resistance in the cells. Gowers considers epilepsy, therefore, as a disease of the gray matter of the brain, most frequently of the cortex, which results in an impairment of the resistance of the nerve-cells to the liberation of energy. A sudden and violent liberation of nerve-force results in derangement

of function and impairs the integrity of the complex state called consciousness.

Whatever may be their differences of opinion regarding the occurrence of arterial spasm during an epileptic attack, neurologists agree that there are intimate and intricate relations between epilepsy and insanity. Of the mental manifestations arising from epilepsy, perhaps the most interesting is the psychical disturbance. In 1850 Morel[1] gave the name *epilepsie larvée*, or masked epilepsy, to attacks of the disease in which there were psychical manifestations. Esquirol followed him in the usage of the term, as also Legrand du Saulle.[2] The latter, in 1877, reported two cases under this name, both of which were cases of double consciousness. In the first of his cases the mental alienation lasted from several hours, in some attacks, to three days in others, during which time the patient traveled long distances, often regaining consciousness in a prison or on a railway train, when he found himself in possession of several articles he had unconsciously stolen. In du Saulle's second case the patient, whose periods of automatism lasted from twenty-four to forty-eight hours, murdered a peaceable old man, a stranger, during one of his attacks.

Among the few cases of psychical epilepsy reported have been included cases of imperfect consciousness, expansive delusions, dreamy states, intervallary insanity, and, in short, all psychical disturbances preceding, replacing, or succeeding convulsions. Should not the term psychical epilepsy be limited to cases in which the epileptic psychic equivalent replaces the epileptic attack of *grand* or *petit mal*, excluding double consciousness? It would simplify the matter if the term were confined to those cases in which a maniacal outburst follows the usual preparoxysmal stage. After a period of despondency, irritability, restlessness, dread, giddiness, or, in some patients, intense elation, in others an exhibition of voracious appetite, instead of a fit the patient experiences a sudden attack of laughing, weeping, or shouting, with extravagant gesture and maniacal appearance, and even in some examples with uncontrollable homicidal impulse devoid of motive.

An argument against the inclusion of all cases of double consciousness, under the title psychical epilepsy, is that this condition, while most frequent among epileptics, occurs also in alcoholic patients and in cases of melancholic frenzy.

Gowers[3] applies the term masked epilepsy, or *epilepsia larvata*, to a condition succeeding a minor attack of epilepsy, in which there are random remarks made and automatic acts performed by the dazed and stupid patient. Imperfect loss of consciousness with automatic action, he remarks, constitutes the minor seizures in some cases without any initial epileptic stage.

Brief notes on two of my cases will suffice to illustrate psychical manifestations in cases of *petit mal*. These are not pure psychical epilepsies.

H. S., an unmarried clergyman under my care, of German parentage and aged twenty-seven, had his first epileptic attack at the age of twenty-four, which he attributed to overstudy, anxiety, and loss of sleep preceding an examination. For several weeks he prevented drowsiness while studying at night by sitting with his feet in cold water. His father was an epileptic. After a minor seizure, during which he stares wildly about and chews convulsively, he walks about, eats, prays, or preaches coherently for about fifteen minutes. During this amnesic period he can carry on conversation, recognizing the members of his family and calling them by their names. All his attacks have been similar and have appeared at intervals of about a week.

A. S., a bookkeeper, aged thirty, married, born in Germany, came under my care after having experienced for at least six months conditions of reduced consciousness occurring every two or three weeks. During his mental alienation, which probably follows an attack of *petit mal*, he wanders off for a week or less, walking about the streets, entering shops and saloons, conducting himself properly, but in an amnesic condition. He has nocturnal attacks, with cry, but accurate testimony regarding them could not be elicited. He has frequent headaches, is irritable and indolent, and his memory is impaired. His pupils are unequally dilated and respond but slightly to light. He is myopic.

Performances of a psychic character following an attack of *grand* or *petit mal* are not psychic equivalents, and should be called post-paroxysmal psychical manifestations. They are due to mental disturbance, but occur as a result of other causes than epilepsy in certain cases.

Spitzka[1] declares that double or alternating consciousness appears to be limited to the mental disturbances of menstruation and to periodical insanity. He also alludes to its occurrence in primary confusional insanity.

An acquaintance of the writer, a scientist of ability and reputation, occasionally rises from his bed at night and, in a condition of partial but amnesic consciousness, writes upon subjects connected with his work. The results are accurate and valuable, and he knows of the occurrences

during his double consciousness only by finding the manuscript on his table in the morning. He is not an epileptic.

Kiernan[1] says: "Unconsciousness is not a proof of epilepsy, nor does a conscious psychosis disprove the epileptic nature of the subject in whom it occurs. All psychoses may occur in epileptics, and be tinged by the coexisting epileptic state. These, however, are not true epileptic psychoses, and need not necessarily present their characteristics."

As examples of the class of cases to which it seems desirable to limit the term psychical epilepsy, I add brief notes of two cases occurring in the practice of Professor M. Allen Starr, who has put their histories at my disposal. A report of the first case has been published.[2]

S. F., aged twenty-one, is the son of healthy and intelligent parents, with a personal and family history free from any rheumatic or syphilitic taint or alcoholic habit. Up to his fifth year he was a bright and healthy child. He then received a severe fall on his head, followed by unconsciousness for twelve hours. Since that accident he never completely regained his mental balance, and has suffered from pain on the left side of his head. He seemed fairly bright at his lessons, and was willing to study, but was very easily excited and accustomed to give way without adequate cause to emotional impulses, either of joy or anger. When sixteen years of age he received a second fall on his head, followed again by unconsciousness for several hours. Since the second accident all his symptoms have been decidedly aggravated. The headache is located by him in the left parietal and occipital regions, and the maximum point of pain seems to be at a point half-way from the parietal boss to the median line, and at this spot a small scar can be seen, and there can be felt a slight irregularity of the surface of the skull, suggestive of a fracture. The pain from which he suffered, though continuous, was subject to exacerbations. In connection with the sudden increase of pain, the boy would develop a maniacal condition, in which his actions were extravagant, his speech abusive and profane, and in which he at times indulged in acts of violence toward his family and employers. In consequence of these attacks, which occurred every few days, or, when under treatment by bromids, every three or four weeks, he was unable to keep up with his classes at school or to pursue any steady employment.

He was not particularly bright or intelligent, though he could not be said in any sense to be demented. Between the attacks he had no clear recollection of what had occurred during the attack, and on several occasions he had lost consciousness; he had never had any convulsions.

It is an interesting fact that this boy recovered after trephining, the operation being performed for Professor Starr by Dr. A. J. McCosh.

The second case, of which a mere outline is quoted from Dr. Starr's copious and valuable notes, is that of W. V. D.:

His father was intemperate and ungovernable. His paternal grandmother and two greatuncles on his father's mother's side were insane. His mother is insane. His father had an epileptic cousin. His mother's father was paralytic and nervous, and one greatuncle was intemperate, and one member of his mother's family had migraine. At the age of three years the patient had screaming attacks and hallucinations of visions (seeing faces). Though very bright, he was ungovernable and and contrary. At seven he had attacks of running about and of laughing, sighing deeply afterward. Between the ages of seven and a-half and nine and a-half he had no attacks, under bromide treatment. At nine he was circumcised. At eleven he had hallucinations of visions—shapes and figures—together with attacks of fear, for one month. At twelve he had laughing attacks at night, making loud blowing sounds. During the following year he had over 1100 attacks of singing, laughing, crying, etc. The bromids being then withdrawn, he had his first convulsion, and ninety convulsions were counted during the subsequent fifteen months. He was conscious of the running attacks, but not of the singing, or laughing, or crying, nor of the convulsions. He has become insane. This case, up to the age of about twelve years, was a case of pure psychical epilepsy.

Attacks of psychical epilepsy are of vast medico-legal importance. Epilepsy is common among the criminal class, and the lower type of epileptic is cunning, deceitful, treacherous, and bold. Egotistic and irritable, he often carries resentment against someone. A mere grudge, in the interparoxysmal periods, becomes the basis of a homicidal attack or other criminal act during an epileptic seizure. Bevan Lewis[1] calls attention to the fact that leading ideas, delusional or otherwise, prevailing in the preparoxysmal stage, are likely to become operative in conditions of post-epileptic automatism and during psychic equivalents. It is a hard task to decide whether an epileptic is accountable and should be punished for crimes committed during a psychical manifestation, equivalent or post-epileptic. The discovery of motive in an interparoxysmal complaint or threat is not enough to satisfy one of the responsibility of the patient for crime committed during an attack. The alienist knows that the epileptic will perform, automatically, complex acts that have the very appearance of deliberate volition. He knows that the patient, under circumstances, is really irresponsible.

A just disposal will be made of these criminals and of the malingerers for whom their legal advocates enter a plea of transient insanity due to epilepsy, when they are promptly confined in a hospital under the eye of a competent alienist, that their interparoxysmal mental state may be studied, and the preparoxysmal and post-paroxysmal stages of subsequent attacks may be observed. Study of the intervallary period will generally prove barren of result; rarely will it afford us

evidence of a mind governed by delusions. Study of the conditions immediately antecedent and subsequent to the attacks will give us evidence as to the presence of genuine automatism, of uncontrollable impulse, of blind fury operating during reductions in consciousness.

CLINICAL MEMORANDA.

MOTOR AND SENSORY APHASIA OF SEVEN YEARS' DURATION, DUE TO PROBABLE THROMBOSIS FOLLOWED BY ANGIOMA; OPERATION; RELIEF OF PAIN; SLIGHT IMPROVEMENT IN SPEECH.

BY J. T. ESKRIDGE, M.D.,
AND
CLAYTON PARKHILL, M.D.,
OF DENVER, COL.

THE following case seems to indicate that the usefulness of cerebral surgery may be further extended.

James S., aged forty-five, single, born in Ireland, a miner by occupation, has been living in Colorado nearly twenty years.[1] Seventeen years ago, while blasting in a mine, he was injured by a flying piece of rock. The right hand and left knee were severely cut and bruised, and the skull was crushed in just above the left eye. He recovered from the immediate effects of the accident, but has suffered from headache in the left frontal region from that time up to the present. Ten years after the injury, he suddenly lost his speech. It is impossible to learn from his history whether he has indulged in alcohol to excess or has ever contracted syphilis. Of the circumstances attending the onset of his loss of speech, I can find out nothing. Three years later, or four years ago, he was adjudged insane and sent to the Colorado State Insane Asylum. During his stay there his speech has been confined to "yes" and "no," which he does not always use correctly, and a few profane words.

On January 27, 1896, during an official visit at the State Asylum for the Insane, through the courtesy of Dr. Thombs, the superintendent, I was permitted to make a thorough examination of the patient.

The gait is good and no ataxic symptoms are observed. All the leg muscles are strong. Dyn. R., 200; L., 232. The right wrist had the tendons severed in front during the mine accident, and this hand is now much cooler than the left one. There is no paralysis of the facial mucles, and the tongue is protruded in the median line. Knee-jerks, R., about normal; L., a little lessened. Ankle-clonus absent. Tendo-achillis, R., slight; L., absent. Deep reflexes of the arms are all increased, the right more than the left. Masseters absent. Sensation: All general sensory phenomena are normal on the left side. Right side, tactile sense lessened throughout this entire side of the body, but least in trunk, thigh, and upper arm, most decided over foot, hand, and face. Localization and muscular sensation lessened. Temperature, pain, posture, and joint sensations, so far as I am able to determine, are nearly normal. Hearing: Watch, R., not at all; L., on contact. Tuning-fork heard with both ears, but it is impossible to determine in which one it is heard most distinctly. Smell present and equal on each side. Taste, he can recognize salt only on the left side of the tongue. Eyes: Central vision, fields, disks, fundi, internal, and external muscles are normal. His memory is good. He often feels dizzy, and at times has a tendency to fall backward. He has a constant numb sensation on the right side of the body, but he experiences no pain. He frequently feels confused, especially when he is trying to concentrate his mind on any subject. He has no delusions and shows no evidence of insanity. He is a strong and vigorous man, enjoys the liberties of the place, and is almost constantly employed in doing chores around the Asylum. He complains a great deal of headache in the left frontal region of the head.

Aphasia.—He recognizes objects and their uses when presented to him through any of the senses on the left side, and through all the senses on the right side, except that of hearing. Considerable time is consumed in testing his power to recognize objects with the right ear. He recognizes a watch, bell, or coins when heard by the left ear. He can hear a loud ticking watch with the right ear, but the sound of a watch, of a bell, or of jingling coins, when heard by this ear alone, apparently conveys to his mind no distinct meaning other than that of noise. He readily recalls the spoken names of objects presented to him through all the senses, except that of hearing on the right side. Sometimes he seems to recall the spoken name of an object heard by the right ear, and at other times he does not. His answers have to be taken with caution, as he says "yes" sometimes when he means "no," and when he becomes fatigued he is nervous and excitable. He seems to understand speech and music on first testing for this power, but it is found that he appreciates fully only the commoner things that are spoken to him. Some things have to be repeated several times before he seems to understand them. If one talks to him in an ordinary conversational style he becomes confused. He has no difficulty in recognizing his own name when it is spoken, or a word when it is spelled aloud. It is impossible to get him to understand what is wanted when I endeavor to test his power to call up mentally the sound of a note, figure, letter, or word. In testing his power to recognize notes, figures, letters, words, or colors seen, it is found that he can do so only for a few. He soon gets confused. He can read nothing aloud, and it is doubtful whether he can read inaudibly so as to understand what he reads, except a few familiar words, *e.g.*, Asylum, Dr. Thombs, Pueblo, etc. He recalls a few familiar objects, the names of which are seen. He does not seem to be able to write voluntarily, nor at dictation. He copies fairly well, both printing and writing, but does so mechanically. He cannot write the name of any object presented to him through any of the senses. He does not understand what he has copied, except when he has copied some familiar words. He cannot be induced to

[1] I am unable, on account of the patient's aphasic condition, to learn anything of his family history, and only a few items can be ascertained concerning his personal history.

try to write his own name, but he reads and understands it when written by another. He does not recognize a letter when his index-finger is made to trace it. It is impossible to determine whether he can call up mentally the appearance of an object, figure, note, letter, or word. He cannot speak voluntarily. His entire vocabulary is limited to "yes," "no," "G— d—d." These words are used automatically, or simply reflexly. He can, however, usually manage to say "yes" or "no" voluntarily when requested to do so. At times he can voluntarily utter his profane expression, but at other times he cannot. The patient cannot propositionize. He understands and uses gesture expression. He can read figures inaudibly, and apparently understands the value of most figures taken separately. He shows no evidence of understanding most numbers above ten. He can add two numbers, but cannot subtract, etc. He seems to recognize money, but it is doubtful whether he appreciates the value of each denomination. He can play cards and other games.

Diagnosis.—The first question to decide was the connection of the injury to the head, which occurred seventeen years ago, with the aphasia, which followed ten years subsequently. Immediately above the left superciliary ridge, there is an old cicatrix, and beneath this, the bone is depressed to a depth of about one-quarter of an inch. The headache of which he complains dates from the time of the injury to the head. As the aphasia did not occur until ten years after the receipt of the blow to the head, it is believed that there is no direct connection between the former and the latter. It is thought, however, that the head injury may have caused a local pachymeningitis, and that this may have extended backward and produced some changes in the cortical branches of the middle cerebral artery. It is thought that the immediate cause of the aphasia was a thrombotic occlusion of cortical branches of the left middle cerebral artery. The aphasia is distinctly motor and sensory in character. The motor aphasia is nearly absolute, the sensory partial. There is no distinct word deafness or mind blindness, but a partial apraxia and mental enfeeblement, as shown by his mistakes in the use of some objects, and his inability to concentrate his mind without becoming confused and exhausted. The existence of the complete motor aphasia prevents a satisfactory test being made of the sensory.

The next question to decide was whether any surgical operation would likely be followed by benefit to the patient. Dr. Clayton Parkhill of Denver, one of the consulting surgeons to the Asylum, was visiting Pueblo at the time of the examination. He was requested to see the patient with me. He was of the opinion that the depressed fragment of bone should be elevated, as this might relieve his headache, but in regard to further surgical procedure, he declined to express an opinion, preferring to be guided by the results of my examination.

After studying the case carefully, I became firmly convinced that there was no direct connection between the old head injury and the aphasia. The cortical area involved by the lesion in the left hemisphere seems to be extensive, and is supplied by the first part of the second, and the fourth cortical branches of the left middle cerebral artery. The main lesion was at the point of the bifurcation of the Sylvian fissure. In view of the marked improvement following excision of the degenerated orolingual center, in a patient operated upon for me by Dr. Edmund J. A. Rogers, at the Arapahoe County Hospital, some two and a half months before the time set for this operation, I decided to recommend excision of the cortical surface of Broca's center in this case.[1]

REMARKS UPON THE OPERATION AND SURGICAL ASPECT OF THE CASE.

By Dr. Parkhill.

Operation, March 1, 1896, 10 A.M.: On elevating the depressed fragment of bone above the left orbit, it was found that the left frontal sinus only had been involved in the injury. The anterior wall had been crushed in, while the posterior was intact. The depressed bone was removed and the sinus scraped out and packed. The measurement on the scalp were then transferred to the bone. A semi-circular flap was raised, with its base downward, and a half inch button of bone removed from over Broca's convolution. The opening was enlarged until it had a diameter of about two and a half inches. The dura was found to be normal. On opening it, however, and reflecting it, an arterio-venous aneurism of the pia was at once preceptible. As might be expected in such a condition, the veins predominated, giving to the surface of the brain a bluish tinge. Pulsation was very faint. The greatest change in the vessels was found over the speech center of Broca, and extended upward and backward in the direction of the horizontal branch of the fissure of Sylvius. The dilated vessels were secured above and below by means of numerous catgut ligatures, and the intervening portion was excised. It was believed inadvisable to enlarge the opening in the bone further in an attempt to remove all of these dilated vessels, as it would make the operation so extensive as to be hazardous to the patient's life. The cortical substance in the region from which the angioma had been removed seemed soft and degenerated, and a considerable portion of this was excised. During the operation there was considerable capillary hemorrhage, which was fairly satisfactory controlled by gauze pressure. Inasmuch, as there was not absolute hemastasis, a small rubber drainage-tube was introduced, the dura sutured around it by catgut, and it was brought out through an opening in the scalp flap. The scalp was sutured with silkworm-gut, and the ordinary dressing for these cases was applied. The patient rallied well from the operation, and showed very little evidence of shock.

On April 24th, Dr. R. W. Corwin of Pueblo, elevated the scalp flap and inserted a disk of gold foil between it and the dura. From this, the patient made an uneventful recovery.

MICROSCOPICAL REPORT.

By Dr. E. R. Axtell.

In the specimen submitted for examination was found a mass which was very soft and pulpy, and which, when

[1] MEDICAL NEWS, August 15, 1896, p. 176.

examined, was found to be composed of dilated blood-vessels having walls which resembled small veins and arteries. A few of the vessels looked like new formed vessels, but most of them seemed to be preëxisting blood-vessels, dilated. Along with this dilatation, there is an increase in the amount of connective tissue. The vessels present a general tubular outline, but show fusiform and sacculated dilatations. Pathologic diagnosis is simple angioma.

FURTHER NOTES ON THE CASE, WITH REMARKS.

BY DR. ESKRIDGE.

The patient was able to be up on the eighth or tenth day after the operation, and at the end of the third week it was observed that he had added to his vocabulary four words: "cold," "snow," and "good morning." He had never been known, since he had been in the asylum, to use the expression "good morning," until about three weeks after the operation, when on meeting the superintendent one morning, and being accosted "Good morning, Jim," he replied "good morning." The words "snow" and "cold" had not been uttered by him before. These words apparently were not uttered entirely voluntarily, as he could not repeat them on being requested to do so. He did not recover his general health very rapidly after the operation, and in consequence the gold foil was not inserted between the scalp and dura until the latter part of April. His headache has been relieved by the operation, and the superintendent of the asylum, Dr. Thombs, says that the patient seems brighter than he has at any time during the previous four years.

On my visiting the asylum, April 29th, a few days after Dr. Corwin had inserted the gold foil, I found the patient in bed, but cheerful and free from pain. At that time, his speech did not seem much better than it did before the operation, but as the wound had been so recently reopened for inserting the gold foil, it could not be expected that if he had made any improvement in speech it would be manifest then, and besides I made no thorough examination to test his speech.

May we hope to benefit old aphasics whose lesions have been limited to the cortex by surgical measures? If so, what is the explanation of favorable results following surgical procedures? It is probable that a degenerated cortex, from occlusion of a vessel, may act as an irritant, and give rise to headache, and exert an inhibitory influence on adjacent cerebral structures, especially on corresponding portions of the cortex in the opposite cerebral hemisphere. The greater the inflammatory condition in the cerebral substance following occlusion of a vessel, the greater the probability of headache and inhibitory influence of the lesion. Removal of the source of the irritation under such circumstances might relieve the headache. Just how much improvement of function may follow removal of the old degenerated portion of the cortex, time, with ample experience, must decide. If nothing more is accomplished by excising softened areas of the brain than the relief of persistent headache, the operation is entirely justifiable.

In regard to the angioma, I am inclined to think that while an abnormal condition of the blood-vessels, involving most of the cortical branches of the left middle cerebral artery, may have existed since birth, the pronounced dilatation of the vessels occurred subsequent to the development of the aphasia, which probably came on suddenly. His speech had been excellent before this. It would be interesting to know the state of the corresponding vessels on the opposite side of the brain.

Further report of this case will be made in about a year.

FORMALIN IN THE TREATMENT OF PURULENT OPHTHALMIA.

BY E. OLIVER BELT, M.D.,
OF WASHINGTON, D. C.

THE following case is of interest, not only in showing the value of formalin in promptly arresting ulceration of the cornea, but also in its remarkable effect upon a large prolapse of the iris, which was reduced, and a round mobile pupil obtained *without anterior synechia*.

On March 13, 1896, I was called in consultation with Dr. W. Sinclair Bowen, to see M. C., a boy of fifteen years, suffering with purulent ophthalmia (specific) of both eyes. The right eye had been affected six days, and was in a very serious condition with only light perception. There was great chemosis of the conjunctiva, a large protrusion of the iris through the lower quadrant of the cornea, and the entire cornea was cloudy. There had been a purulent discharge from the left eye for two days, but the cornea was still clear, and there was no chemosis. The treatment had been nitrate of silver solution, two per cent., once a day. Boracic acid solution hourly when the eyes were bathed freely with hot water. To this was added, for the right eye, free scarification of the conjunctiva daily, and atropin sol. Bichlorid solution, 1–4000, was substituted for the boracic acid. However, both eyes got worse, and in a few days there was considerable chemosis in the left eye. Ice compresses were then used on the left eye, but in two days the cornea became cloudy, and was soon sloughing at the lower segment. At this time, Dr. Burnett suggested the use of formalin, and a solution of 1–1500 was ordered every hour instead of the bichlorid solution. Eserin had been substituted for the atropin the day before. Once a day the sloughing cornea of each eye was touched with formalin solution, 1–60. The second day, the slough had disappeared from the left cornea, leaving a clear ulcer. On the third day, there was considerable improvement in the right eye, and the chemosis was disappearing in both. In ten days, the left cornea was clear, no chemosis, and very little discharge. The prolapse of the iris in the right eye had shrunken greatly. In one month, the left eye was normal, V. $\frac{2}{2}\frac{0}{0}$, with no clouding of the cornea. There was no sign of hernia of the iris in the right eye, except some pigmentation of the cornea, where the iris had been incarcerated. There was no adhesion of the iris to the corneal wound. The iris had resumed its normal position with a circular pupil. Though not transparent, the clouding of the cornea was not dense, and he could count fingers at six inches. From the constant progress of the

disease until formalin was used, and its rapid subsidence immediately following, I am quite convinced that the eyes would have been lost but for its use. I believe formalin is especially valuable in arresting corneal ulceration, and in lessening corneal opacity.

MEDICAL PROGRESS.

Varicella of the Larynx.—M. MARFAN and J. HALLE (*Revue mens. des malad. de l'enfance*, 1896, Januar). One of the rarest diseases to come under the observation of the clinician, is varicella of the larynx. The authors describe two cases, which came under their care, as follows:

The first case was a boy of three years of age. He was suddenly seized with great difficulty of breathing and fits of suffocation. Inspection of the oral cavity, together with a bacteriological examination, gave no evidence of diphtheria. On account of the cyanosis, tracheotomy was performed. There was no membrane. After an injection of antitoxin, the typical eruption of varicella appeared on the forehead, neck, cheeks, abdomen, and back. The same eruption appeared on the body of a younger brother of the patient. After a little while the breathing became normal and recovery supervened.

The second case was a child of nine months. The typical eruption was distributed over the greater surface of the body. There was marked stridor and difficulty of breathing. Examination as to the presence of diphtheria was negative. Nevertheless, an injection of 20 c.c. of antitoxin was given. Broncho-pneumonia and copious diarrhea followed, and death was not long delayed. The *post-mortem* examination revealed a circular shallow ulceration on the posterior part of the right vocal cord, about the size of a pea (a burst varicella vesicle). The prognosis of laryngeal varicella is extremely dubious. As yet, statistics furnish but one recovery. Treatment consists in either intubation or tracheotomy. Stenosis of the larynx in varicella may at times be confounded with diphtheria. A bacteriological examination will serve to distinguish the two.

Latent and Masked Tuberculosis. — In the *Berliner klinische Wochenschrift*, 1896, Nos. 19, 20, and 21, PROFESSOR E. MARAGLIANO speaks of latent tuberculosis as that condition in which, notwithstanding the tissue changes due to the invasion of the tubercle bacillus are progressing, we yet fail to elicit any symptoms which might reveal their presence. In these cases, the intercurrence of any depressing factor, such as pregnancy, a slight disorder, mental depression, insufficient nutrition, is generally sufficient to convert this latent process into a process which mostly passes for one of spontaneous activity. Frequently, such general symptoms as fever, wasting, etc., are present, though the most careful examination fails to detect any local physical changes. Clinically, two types—the dystrophic and the typhoid are recognized. In the dystrophic type, the progressive wasting, anemia, loss of appetite, and cessation of the menses, show a marked disturbance of the functions of nutrition. The prominent symptom of the typhoid form is fever. This may be either remittent or intermittent and, at times, so high as to suggest the existence of typhoid fever. The not infrequent coexistence in these cases of splenic enlargement and an exanthema may lead to an error of diagnosis. The frequent unavailability of the physical and microscopic methods of examination, renders the diagnosis of the latent and "masked" types of tuberculosis, at times, very difficult. An available method in these cases may be found in determining the toxicity of the blood-serum. The injection of a few centimeters of blood-serum, in which the toxic products of the tubercle-bacilli are present, will suffice to kill a rabbit. A still more practical method consists in the characteristic reaction obtained by the injection of tuberculin.

Resection of the Fifth Costal Cartilage as a Preliminary Step to Incision of the Pericardium. — DURAND, in the *Rev. de Chirurgie*, June, 1896, urges the advantage of resection of the fifth costal cartilage before opening the pericardium. He holds that it is assuming an unwarrantable risk to plunge a trocar blindly through the intercostal space, without knowing if the pleural cavity is traversed or not. Moreover, resection of the cartilage gives an opportunity for free drainage of the pericardium. The operation can be readily performed under cocain. The incision is made over the cartilage from the sternum outward. The cartilage is bared, divided at the sternocostal joint, lifted and divided at its junction with the rib. The perichondrium is removed with the cartilage. The reflection of the pleura is next observed and avoided, and the pericardium opened as widely as the case demands. It may be necessary to remove the margin of the sternum with a rongeur to reach the uncovered pericardium.

THERAPEUTIC NOTES.

Diverticulum of the Gall-bladder.—STAUB mentions a case of a diverticulum of the gall-bladder caused by a calculus. The diverticulum was above, and simulated the gall-bladder, while the bladder situated below might well have been taken for a floating kidney. A cholecystotomy resulted in a complete cure.

Treatment of Spinal Meningitis with Hot Baths.—J. WOROSCHILSKY (*Therap. Monatsch.*, February, 1895). At the suggestion of Aufrecht, the author treated two severe cases of spinal meningitis, in which the other methods, including the calomel treatment, had failed, with hot baths.

In both cases good results followed.

A warm bath (103° F.) was given every day of ten minutes' duration.

In the one case, after eight days of this treatment, a marked improvement was noted.

In the other case, complete recovery took place after the fifteenth bath.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, SEPTEMBER 5, 1896.

CREOSOTE IN TUBERCULOSIS, BURLUREAUX METHOD.

THE use of creosote in pulmonary and other forms of tuberculosis has an ardent supporter in Burlureaux, *Gazette Heb. de Med. et Chir.*, July 19, 1896, who asserts that the intolerance of the organism for this drug is a reliable indication of tubercular degeneration. The case is stated by him in three aphorisms. (1) Every patient who does not tolerate very small doses of creosote is almost surely beyond hope. (2) Every patient who bears creosote well in large doses has excellent chance of recovery. (3) If a patient has borne large doses of creosote well, and later becomes unable to do so, the prognosis is rendered thereby a most serious one.

Burlureaux rejects stomachic and rectal methods of administration of creosote, because he believes that a surer effect and a larger dose accompany its subcutaneous use. For this purpose the ordinary creosote of commerce is redistilled at 207° C. (404⅗° F.). This gives a creosote pure, except that it contains from eighteen to twenty per cent. of guaiacol, which is not objected to. The creosote is then mixed with from fourteen to twenty parts of sterilized olive oil, and is injected *subcutaneously* if the dose is large—*into a muscle* if only a small amount is required. A child from one to five years old should receive ♏1 to ♏7 daily; an adult ♏15 to ʒ 1, or even as high as ʒ 4. These amounts are of the creosote, not of the mixture.

There is usually no immediate effect of the injection if the oil is forced slowly into the tissues. In a small percentage of patients (one per cent. in males, ten per cent. in females) considerable pain is experienced. A blood-vessel is naturally to be avoided.

Sometimes pain begins soon after the injection and lasts from two to three or even five hours. Within a few minutes the odor of creosote is noticeable in the breath, and the patient perceives its taste. The urine may also be discolored, and this discoloration is an index of the prognosis—if slight, the prognosis is good; if marked and invariably present, the case is wellnigh a hopeless one. Perspiration after injection is another unfavorable sign; but the worst symptom of all is a subnormal temperature, with chilly sensations appearing about seven hours after injection, especially if long-continued. The temperature may sink even to 95°. This symptom is a contra-indication for the use of creosote, or at least its use in large amount.

Burlureaux has treated in the manner described 262 cases, over two hundred of whom were much improved in health as a result of the creosote.

THE SANITARY CONDITION OF MEDICAL SCHOOLS.

PERHAPS the public thinks, if it thinks at all, a medical school is a most sanitary institution. But probably no more conspicuous example of inconsistency, of failure to put into practice what the faculty is daily teaching in reference to hygiene, exists than is to be found in the amphitheater of the average medical school. In most institutions smoking and spitting on the floor is not only allowed, but it is actually expected. The vulgar applause with which the students greet the arrival of a favorite professor stirs up clouds of dust, which rise from the filthy floor and float in the atmosphere for hours, till it has been inhaled and reinhaled by the heedless students. In

a great many medical schools a large number of the students fall victims every year to these unsanitary surroundings. In some schools the percentage of students annually attacked with tuberculosis has been as high as three or four per cent. In the graduating class of the college with which the writer is associated four men out of fifty acquired tuberculosis during their course, and one of these will probably not live out the first year of his practice.

It has been frequently remarked that students who leave college and take positions immediately as hospital internes are very liable to show signs of tuberculosis before they finish their hospital service. Considering the usually vigorous class of young men who make up the body of medical students, this is entirely too great a ratio, and speaks loudly against the continuance of the unsanitary condition of the lecture-rooms. The amphitheater is particularly liable to neglect. On account of the arrangement of the chairs and their backs, the floor is invisible. A decent appearance is presented to the faculty when the arena alone is clean. Long hours, bad air, imperfect heating, and constant inspiration of tubercular dust has been the ruin of many bright young medical students, some stricken down during their college course, others at the end of it, and still others succumbing during the immediately succeeding years. Is it not due to the preservation of our professional self-respect that our medical schools be thoroughly investigated and during the present vacation put in the most sanitary condition possible, and that such rules and regulations be made and such changes undertaken as will secure hereafter not only a decent and dignified audience-room, but one which shall not endanger the lives of students and teachers?

THE CAMERA IN THE DETECTION OF CRIME.

The vogue of the Röntgen ray and the skiagraph continues. The great Li Hung Chang is said to have been comforted, and to bear with equanimity his historic loss of the yellow jacket and the peacock feather, now that he has found, by means of the "X-ray," the Japanese bullet he carries in his head. But in spite of the vogue of the new imponderable, the photographic camera continues to add to its achievements and to offer enlarged possibilities to the student of medical jurisprudence. The camera reproduces differences that the human eye cannot perceive, and frequently represents objects with a wrong distribution of light and shade, because there are colors which are not visible, but which possess actinic power.

The experiment, familiar to some, of photographing a practically invisible drawing made with a solution of sulphate of quinin in water, and getting a clear, sharp result in the photograph, owes its success to the fact that quinin has the power of converting the violet, ultra-violet, and blue rays into rays of less refraction. Treatment of surfaces to be photographed with substances having powers similar to the power of quinin, and the employment of various sensitizers in gelatin emulsion put within our reach, results which, a generation ago, would have been deemed magical.

From the *Tägliche Rundschau* we learn of a practical use of photography in the detection of crime that is novel and ingenious. The murder of a woman was traced to one of two men—her husband and a neighbor. Each had hairs upon his clothes. Dr. Jeserich, "the inventor of criminal photography," photographed the clothes of the suspected men, and the camera disclosed the fact that the hairs on the husband's clothes were from his wife's head, while the other prisoner had hairs from his own head on his clothing. The same scientist has shown that the differences in inks used in writing and in altering a document can be shown clearly in a photograph of the document. Even on surfaces from which, to the eye, all trace of writing has been erased, the camera reveals legible characters; and the forger or thief fails of his purpose of irrevocably destroying the original purport of the document with which he tampers. Were all possible agencies known to science used by scientists in the detection of crime, these would be "troublous times" for malefactors.

ECHOES AND NEWS.

Illinois Licenses Midwives.—The Illinois State Board of Health at its meeting in July, passed a resolution allowing midwives to practise in Chicago. Applicants will have to submit to a thorough examination and give satis-

factory proof that they are capable of doing their duty, and file a bond with the Board.

A New University Building.—The University of Pennsylvania is erecting a building for the department of dentistry, to cost $120,000.

Medical Journalism in Paris.—According to the *Annuaire de la Presse*, the number of medical journals published in Paris has fallen from 191 in 1895 to 175 in 1896.

American Public Health Association.—The twenty-fourth annual meeting of the American Public Health Association will be held at Buffalo, N. Y., September 15th, 16th, 17th, and 18th.

Typhoid Fever in New Haven.—Upward of seventy cases of typhoid fever have now been reported in New Haven. All of these are believed to be traceable to the milk delivered by one dealer.

An Endowment Fund for the Royal Victoria Hospital.—Lord Mount Stephen and Sir Donald Smith have given $800,000 to form an endowment fund for the Royal Victoria Hospital, Montreal.

Typhoid Fever in Chicago.—Typhoid is reported to be again on the increase. No particular locality seems to suffer in excess of others, but the disease is gaining a a general hold on the city.

A Texas Donation.—The University of Texas has received $30,000 from Col. W. C. Breckinridge of San Antonio, to be used in building a refectory and dormitory for the women medical students.

Indianapolis to Try Sand Filtration.—The recommendation of the Board of Health of Indianapolis that intermittent sand filtration be introduced into their water system has been approved. The filtration of 2,500,000 gallons per acre has been adopted as the limit.

The First Women Doctors from Edinburgh.—Miss Jessie Macgregor and Miss Mona Geddes, of Edinburgh, were two of the 151 medical graduates from Edinburgh University in the class of 1896. They are the first women to take medical degrees from that institution.

Sewage-Farms in Paris.—One-fifth of Paris sewage is used to irrigate waste lands. The municipal council acquired a tract of 2000 acres of arid, sandy soil in the forest of Saint Germain, two years ago, and irrigated it with sewage. It is now bearing luxuriant crops.

Dr. MacDonald's Successor.—Dr. Carlos F. MacDonald has resigned the presidency of the New York State Lunacy Commission and Dr. Peter M. Wise has been appointed his successor, the appointment to take effect October 1. Dr. MacDonald, whose term would expire by limitation in May, 1901, will resume private practice.

Sponges as Septic Agents.—Professor Lang of Vienna, in a recent work, "Hygienic Hints," declares that sponges, on account of the impossibility of destroying the bacteria in them, have long since been banished from the operating-table, and that their exclusion from the bathroom and washstand should follow.

A Lucid Definition.—A recent German writer in a work recording observations on psychic phenomena in animals, including man, concludes that soul or spirit is a force emanating from the nervous system, stimulated and modified by the physical organism under the manifold influences of the outer world.

The English Stage-Stabbing.—The inquiry into the death of the actor who was stabbed to death recently, at a London theater, by a too realistic villain, showed that the dagger pierced the front border of the lung, the pericardium, and aorta. In spite of the mortal nature of his injury, the wounded man was able to answer a question and allowed the curtain to be raised.

The Philadelphia Polyclinic.—The annual catalogue announces that the faculty of the school has been increased and its facilities enlarged, especially in its laboratory equipment. An excellent Röntgen apparatus has been provided for daily use in diagnosis and study. Nearly sixteen thousand new cases were treated at its dispensary last year, and over five hundred major operations were performed.

Tesla's Theory of the Roentgen Rays.—An exhaustive study of this new form of electric force, causes Mr. Nikola Tesla to reaffirm his belief that the rays consist of streams of minute material particles projected with great velocity. In this idea Mr. Tesla stands alone, as most authorities are agreed that this influence is propagated by means of vibrations in an imponderable ether.

Anesthetics in Great Britain.—The latest report on chloroform as an anesthetic by the *Lancet's* board of investigation seems likely to lead to the rapid introduction of a combination of nitrous oxid with ether. British surgeons have objected to ether, principally on account of its slowness of operation and the distress it causes many patients; but these difficulties have been overcome by the preliminary use of the nitrous oxid.

An Argument Against Pessimism.—Mr. Wilfred Ward, in an account of conversations with Huxley contributed to the *Nineteenth Century*, quotes him as having said: "One thing which weighs with me against pessimism and tells for a benevolent Author of the universe is my enjoyment of scenery and music. I do not see how they can have helped in the struggle for existence. They are gratuitous gifts."

How Best to Make Society Meetings of Personal Value.—Do not try to hear all the papers. Pick out those you are most interested in. Listen to them intently. Come forward where you can hear. Argue with yourself as to the statements made. Discuss points that you want light upon. Refute statements with which you disagree. Do not allow your neighbor to talk to you while you are listening to a paper. If your power of attention lags, get a good breath of fresh air.—*Col. Med. Journal.*

Water Supply of Cleveland, Ohio.—This water supply is drawn through an intake constructed at the expense of

several million dollars—a tunnel extending under the bed of the lake a distance of 8642 feet to a crib. Theoretically, the currents render the water about the crib safe, but storms and counter-currents running eastward, often force polluted water into the pipes. The water has been degenerating steadily. The city has concluded to make a large expenditure to lengthen the tunnel, purify the river, and erect a garbage crematory.

Sunstroke at the Seaside.—*The British Medical Journal*, after reporting a case of sunstroke in an infant, says: "This is but an example of the evil effects of a practice which can be seen in full swing at any of our seaside watering-places—little children 'paddling' with their clothes tucked up, their feet chilled and their heads exposed to the blazing sun. No doubt they enjoy it, but the danger is very great. The thickness of the child's skull and of the soft parts covering it is less than in the adult, and the fact that in some cases when recovery takes place permanent paralysis results, shows that definite local mischief is produced in the brains of patients attacked in this way.

Transmission of Insanity.—John Turner, in the *Journal of Mental Science*, gives some figures upon the frequency of hereditary insanity, based upon the study of 1039 cases observed in the Essex County Asylum. The daughters appear especially to suffer from the insanity of the parents, but the insanity of the father appears to be more often hereditary. Thus, 106 insane fathers have had 117 sons and 138 daughters affected with insanity, while 256 mothers have transmitted the insane taint to 113 sons and 182 daughters. These figures confirm Darwin's law of heredity, according to which the characteristics of the father are more often transmissible to the male line, those of the mother to the female line.

Foreign Medical Students in France.—Some over-ardent French patriots have lately started the theory that no foreign medical men should be allowed to practise in France; and further that something should be done to restrict the number of foreign medical students, who come in greater numbers each year to benefit by the superior knowledge and science of the great French doctors. It seems that 433 Russians, 217 Bulgarians, 211 Roumanians, 204 Turks, 82 Greeks, 83 Egyptians, 70 Swiss, 112 Germans, 100 Americans, 47 South Americans, 6 Japanese, and 8 Persians, are now inscribed as students in Paris, and of these, by far the greater number, join the medical schools. The foreign students, as a whole, are divided into 1489 men and 339 women.

The Size of French Families.—Francisque Sarcey, commenting in the *Cosmopolitan* on one item of the last French census, says that in France not only are large families rare exceptions, but when met with they are sure of being ridiculed rather than admired, and no theatrical joke is more certain of applause than "the appearance on the stage of an Englishman and Englishwoman followed by fourteen or fifteen children, ranged in regular gradation like steps of stairs. Fecundity is in French mothers of families a sort of blemish. When a young wife presents her husband with an heir, it is bad enough; if a second comes, she is pitied; if a third is on the way, those interested are angry, and the indifferent keep away; if a fourth—oh! if a fourth, there will be an explosion of indignation against the tyrant of a husband, of pity or of ridicule for the wife. But never fear—they are not likely to expose themselves to it. Among the middle class, and especially among the Parisian middle class, families with one or two children are the rule. There has just been founded, under the presidency of Mme. Destillon, a league, the object of which is the encouragement of large families.

SELECTION.

THE HYGIENE OF WATER SUPPLY.[1]

By ALFRED SCHOFIELD, M.D.

WATER, when pure, is not a dubious mixture, like air, of gases in various proportions, but is, as we know, a definite chemical product, formed by the union of two volumes of hydrogen with one of oxygen, the three volumes condensing into two as the gases change to a liquid. We say "when pure," for seldom indeed is this interesting fluid composed of these two gases alone. We hear a good deal about the "adulteration of food" act; but all the adulterations of food put together, or of other beverages, are not to be compared in importance with the adulteration of water. We will prove our words further on.

Meanwhile, consider what a tricky sort of fluid this innocent compound is. In the first place, it is protean in form: it can be in turns a solid, a liquid, and a gas. But that is not all. Fluids, as a rule, expand with heat; water, however, at 32°, when heated, begins to contract in volume until 39° are reached, from which point it expands. Water just about to freeze at 32° is therefore lighter than the water 7° warmer, and hence rises to the top—one result being that ice forms on our ponds first at the top, and not at the bottom. Another painful eccentricity of water when it freezes is that, instead of contracting still more in its change from liquid to solid, it has the truly exasperating quality of expanding one-eleventh of its bulk, bringing destruction and ruin thereby into all our houses by burst pipes and boilers.

If we take water at its other extreme—that of heat—its behavior becomes positively weird. In its change from gas to water three volumes were reduced to two; in its transformation from water to vapor two volumes do not become three, as we should naturally expect, but over three thousand! It is true that while the one volume of water is incompressible, these three thousand are elastic; but this is only what we should expect. It is this mighty increase in bulk and elasticity that makes steam the mechanical power of the universe.

Steam, again, contains an immense amount of what is called latent heat, as it requires nearly one thousand times as much heat to raise boiling water into steam as to raise water from 211 to 212°. We merely mention this in

[1] Abstract of article in the *Eclectic Magazine*, taken from *Leisure Hour*.

passing, as we do many other facts, by way of remembrance, and not to reduce these pages to the level of a class-book. We emphasize this point of the latent heat of steam, however, to bring intelligent opinion to bear upon the immense superiority of steam as a disinfectant compared with hot air. Air at 213° is 213° and nothing more, and very soon gets below this; but steam at 213° has a reserve force of latent heat in the background that renders it immensely more efficacious in destroying spores, penetrating as it does into the folds of the infected articles, and gradually parting with its latent heat.

The sources whence we obtain water are mainly five in number—one from above (the rain), two from beneath (wells and springs), and two on the earth's surface (upland waters, such as lakes and reservoirs and rivers).

It is generally supposed that rain water, at any rate before it reaches the earth, is absolutely pure. Such, however, is not the case. In the first place, in England all the rain water contains on an average about two grains of salt per gallon. Then it always washes the air through which it passes, and hence, before it reaches the earth, is laden with spores and germs, and dust and particles of all sorts. Even if it were pure, it is sadly deficient in quantity; for the rainfall in England would not supply above fifty people per acre, although nearly 3700 tons of rain per annum fall on every acre. Rain water is not very palatable. If used for drinking, it should be stored in stone or slate cisterns underground, as at Gibraltar.

With regard to the surface waters, no river in England is long enough to purify itself from the sewage that falls into it. Naturally river water is extremely pure, and is much less hard than spring water, and would form a good drinking-water but for the reason given above. Nevertheless, London, as the largest city in the word dependent upon river water, draws up daily nearly one-third of the whole river Thames. Of course such water cannot be used directly, but requires the most careful filtration. The water is allowed, first of all, a week to settle in reservoirs, to give the coarser sediment time to settle, and it is then run off on to the filter-beds, which are several feet thick, and constructed of very fine sand upon the surface, with coarser sand and gravel below. The real filtering agent is the inch of fine sand, and until lately, whenever this had been used a short time, it was removed and well washed.

A most extraordinary revolution in filtration has, however, been brought about by our recent discoveries of the purifying and antiseptic powers of microbes. We knew they are the scavengers of the earth, but were slow to understand that they might with ease be pressed into our service and compelled to do our dirty work to order. A layer of mud containing millions of germs to the cubic foot is spread over the surface of the sand, and so far from being cleansed from impurities, it is never changed as long as the water will pass through. The result is wonderful. A jelly-like mass, consisting largely of living organisms, forms on the top, which is the real filter. These germs seize on and oxidize all organic matter so completely, and are themselves so incapable of penetrating the layer of sand beneath, that the water thus filtered is far purer than that passed through the purest sand. By this extraordinary means a living filter is constructed, and the bacteria are compelled to do our work just as if they were day laborers or other drudges. Of this water, Londoners consume some thirty gallons per head (being double the amount allowed in Berlin), over 120 million gallons being supplied daily for the direct use of the people.

Upland surface water is very much purer and better for drinking purposes. It is also very soft, and great cities are increasingly looking to lakes for their supplies, and, if these do not exist, are creating them as needed, often, indeed, thereby rather enhancing the beauty of the neighborhood than destroying it. Liverpool, Manchester, and Glasgow are now all supplied by this means.
greatest success.

As to springs and wells, the water varies considerably. Of course, all that comes from deep sources is, as a rule, pure, but shallow wells in towns and villages are an unfailing source of disease, owing to their contamination. In cottage gardens we frequently find two holes dug—one for sewage, the other being the well; and in some cases, where the soil is porous, this is deemed a positive advantage as regards the sewage, which leaks out so quickly as to save the trouble of emptying! Where it leaks to is generally the nearest well; and it is perfectly surprising to see how bright and clear the water often is from these "sewage" wells; and not only so, but how the constitutions of the natives can resist the sewage poison for years, though drunk daily. The leakage, which may have gone on for an indefinite time, perhaps, is only discovered at last by an epidemic breaking out from some disease germs imbibed. Of course the water will not keep, and becomes very foul and muddy after rain.

Deep wells always draw their supply from beneath some impervious stratum, beyond the reach of any surface pollution, and the water often comes from a distance, where this stratum rises to the surface.

An interesting experience near Liverpool shows that the new red sandstone is not always to be trusted. A deep well was bored into it at Liverpool nearly five hundred feet, all being carefully bricked except this part in the solid rock. The result was that, there being large fissures in the rock, the shallow wells, many of them impure, for some distance round, were drained dry into this deep well. The villagers, seeing these wells of no further use as wells, utilized them as cesspools. These gradually drained, of course, also into the deep well, the water of which soon became so foul it had to be closed, a complete system of drainage provided for the district, and it was eighteen months before the water became sufficiently pure to be used.

We may sum up good and bad drinking-waters by saying that springs, deep wells, and upland surface waters are, as a rule, wholesome; that stored rain and lowland surface waters are suspicious, and that shallow well and sewage river waters are dangerous.

Just lately, again, river waters have risen in repute, for it is found, if free from actual sewage, the germs in them have an antiseptic power rather than a destructive power on the human frame, and are thus more active for good than a pure distilled water that contains nothing but hy-

drogen and oxygen. It is, indeed, only gradually that we are getting over our insensate horror of all germs, and are beginning to discriminate between good and bad.

Water may be pure and wholesome and yet not palatable. Distilled and boiled waters are instances of this, and the reason of their tastelessness is that they contain no air. They become palatable if poured over toast.

Water is called "hard" and "soft" according to the amount of lime and magnesium salts it contains, if not more than six grains per gallon, or, in other words, six degrees of hardness, it is called soft, if more, it is called hard. If the salt is carbonate of lime, it is called temporary hardness, because the salts can be deposited by boiling; if salts of magnesium, it is called permanent hardness, because boiling does not remove them. The latter is much the more injurious.

It has long since been found that for water-pipes inside a house, where so many twists and turns are requisite, there is no material so convenient, so durable, as lead. Soft water, however, flowing through lead pipes, dissolves at once a small portion of the lead, and rapidly produces symptoms of lead-poisoning in those who drink it. One-tenth of a grain per gallon is sufficient to produce them.

The purest, softest waters act most rapidly upon lead; on the other hand, if hard water is used, it forms at once a coating inside the lead-pipe, completely protecting it from entering the water. Hard water, therefore, is so largely used, not only because it is so readily attainable, but because it is such a safe water for domestic purposes. On every other ground it is a nuisance.

This protective coating of our lead-pipes gives us a hint, if we possess lead cisterns, not to have them scraped when cleaned, so as to remove this coating on the surface, but merely wiped with a soft cloth. Too much zeal in this case might readily do a great deal of harm.

Moderately hard water is not injurious for drinking, and is very palatable; but if it is very hard, and particularly if there be much permanent hardness in it, it is bad, especially for those who have any predisposition to gout.

The appearance of water is absolutely no safeguard; sewage water containing every form of organic impurity, may, as we have said, be perfectly clear, and is very often sparkling. We have also shown that among those who are accustomed to its use it may be drunk with impunity for years, and is even stated to be absolutely fattening! No water is really safe to drink unless its source be known and its purity beyond suspicion, or it be *boiled*.

There seems to be, unfortunately, a not unnatural prejudice against the use of boiled water. It is insipid and not always quite cold. Under these circumstances, the British matron is apt to fall back on the domestic filters. This is, indeed, a disastrous and dangerous error.

A filter, as a rule, is kept in the basement, and, although regularly supplied with water, at any rate when the family are at home, is seldom or never cleaned. Recent researches, unfortunately, show that, whether it be cleaned periodically or not, it is no absolute safeguard, for it has been clearly proved that all ordinary filters, after a day or two, largely increase impurities in the water. They are, indeed, germ manufactories; and water comparatively free from germs obtains innumerable organisms when passing through an ordinary or neglected filter. The idea of straining off impurities by charcoal and other powders is good enough if the water to be filtered contain any impurities coarse enough not to escape; but we may be thankful that all the water supplied to our houses has been already filtered with more thoroughness than we can do it at home. All filters should be banished from the house rather than so used as to accumulate and distribute germs.

There are perfect filters, the use of one of which has decreased the number of cases of typhoid fever in the French army over sixty per cent., and which absolutely strains off all germs. In these filters the water has to force its way through the microscopic pores of unglazed porcelain or fossil clay, which are small enough to strain off the minutest organism. Even these filters have to be placed in boiling water every other day to keep them in perfect order; but this entails very little trouble.

With regard to aerated waters, we must always remember there is no absolute safety in drinking them if they are artificially made. Natural effervescing waters, bottled at the spring, are presumably quite safe. We mention this because so many traveling abroad, and distrusting the water of Continental hotels and restaurants, take refuge in siphons, which may be quite as dangerous.

The two principal diseases conveyed by water are typhoid fever and cholera. Nearly every outbreak of typhoid fever has been traced to impure water. If nothing but boiled water were drunk by the community, it would do more to stamp out typhoid fever than any other means that can be conceived. Of course in this we include the water so frequently found mixed with milk. If we are to drink, therefore, nothing but boiled water, it means we must boil all our milk as well.

There can be no doubt that the extent to which typhoid fever still prevails in England is a disgrace, for it is not only a preventible disease, but one without any redeeming quality. It kills people quietly, in large numbers, without any sensation; therefore people are not as afraid of it as they should be.

Cholera differs from this *toto cælo*. It is undoubtedly our best sanitary inspector. Most of the drastic reforms that have been carried out in sanitation throughout Europe have been suggested by Inspector Cholera. This disease is still a terror; and so long as it continues so, it is difficult to say whether it destroys or saves the most lives. All our ports have been put in drawing-room order, under the orders of this Inspector.

Cholera is undoubtedly a water-borne disease. The classical case that inaugurated the epidemic of 1866 is well known. A man in Southampton traveled up to town and took lodgings in a house in the northeast of London, near the Lea. He there had a mild attack of cholera, with the result that the water of the river was contaminated. The water company that derived its supply from this polluted stream unfortunately happened at the time to have its filtering-beds out of order for twenty-four hours, with the result that the cholera germs were distributed widely enough to cause the deaths of 16,000 peo-

ple. Of course, if the 16,000 had boiled their water they might have escaped. It does not matter where we go, whether to India, Mecca, Hamburg—where the last outbreak left its plainly written lesson—or Marseilles, the epidemic is caused and spread by drinking dirty water.

The river at Marseilles received its cholera germs in a remarkable way. Twenty corn-mills discharged their refuse into it, the corn coming from Russia and India, where it had been trodden out and handled in cholera-stricken districts. The condition of the Holy Well at Mecca is wholly indescribable in these pages.

Perhaps, indeed, we have said too much already; and yet it is not too much if it leads every reader henceforth to forswear unboiled water, unless derived from a known and perfectly pure source.

SOCIETY PROCEEDINGS.

CANADIAN MEDICAL ASSOCIATION.

Twenty-ninth Annual Meeting, held in Montreal, August 26, 27, 28, 29, 1896.

(Specially reported for THE MEDICAL NEWS.)

FIRST DAY.

THE meeting was called to order by DR. THOS. G. RODDICK, M.P., chairman of local committee. After a short, but warm, address of welcome to the 170 delegates in attendance, Dr. Roddick resigned the chair to Dr. James Thorburn of Toronto, and the general session was opened. The visitors introduced were: Dr. Osler of Philadelphia, Dr. Cushing of Boston, Drs. G. L. Curtis and A. R. Robinson of New York, Dr. Collard of Sing Sing, Dr. J. C. Webster of Edinburgh. The first business was the calling together of the Committee on Interprovincial Registration. This large committee of twenty-seven, under Sir Jas. Grant, retired to deliberate.

The first paper presented was a discussion of

THE RELATION BETWEEN LEUKEMIA AND PSEUDO-LEUKEMIA,

by DRS. C. F. MARTIN and G. H. MATTHEWSON of Montreal. Blood observations have not fulfilled the expectations of sharp diagnosis. Anemia and pernicious anemia, tuberculosis, anorexia nervosa, sarcomata, give appearances which render diagnosis debatable. Bone-marrow and bone changes are occasionally absent; macroscopic and microscopic appearances are interchangeable. True leukemia and Hodgkins' disease the authors consider cases of increased leucocytosis; the conditions, however are uncertain and inconstant. Cases were related from the Pathological Department of Royal Victoria Hospital, in which aberrant and abnormal blood-cells only tended to confuse the diagnosis.

A preponderance of mononuclear cells or myelocytes is not trustworthy. In a case which proved to be trichinosis, sixty per cent. of eosinophiles were found. The authors consider all leucocytes of similar origin, and from microchemistry gather all into one group, if no local disease be discoverable.

The members were next taken by special electric cars to Montreal General Hospital, where a number of extremely interesting cases were shown, among the number a case of successful excision of gastric ulcer in a woman of twenty-four years. Drainage was effected through the abdominal wall. Some months after the operation a stitch worked its way out, leaving a small fistula in wall over stomach. Dr. Kirkpatrick was the operator. An interesting brain case was that of a man with fracture of the skull and serious brain hemorrhage from a bicycle accident. Dr. Shepherd trephined and removed blood-clot. Much difficulty was met with in arresting hemorrhage, but all seemed well. In four days there was recurring bleeding, which was only controlled by tying the common carotid. The wound was stuffed with iodoform gauze, and perfect recovery followed. A case of stricture of the urethra, which had gone on to malignancy, was shown. All the soft parts down to the prostate had been removed. Among the medical cases were: Progressive muscular atrophy of two years' duration, which had begun with pains in the legs; disseminated sclerosis in a man; multiple peripheral neuritis in a child of 4½ years, with great emaciation; a case of cervical rib of the left side in a woman; a case of urticaria, producible at will, had on his back "C. M. A., 1896," in honor of the visitors; several cases of scleroderma, doing well under thyroid extract; flatfoot successfully treated by Whitman's plates; an Italian navvy with true scorbutus was shown by Dr. G. G. Campbell; treatment, vegetables and lemons.

At the afternoon session, DR. MEEK, London, Ont., read a paper on

SOME CASES OF ABDOMINAL SECTION FOR CONDITIONS COMPARATIVELY RARE.

One case was a fibro-cyst of uterus; another, sarcoma of left ovary: another, volvulus from flexure of the colon in a man; all went well for ten days, then the patient died maniacal. A case of congenital absence of auditory meatus was shown.

DR. R. FERGUSON of London, Ont., read a paper on

OPHTHALMIA NEONATORUM.

Authors estimate that from ten to twenty per cent. of the blind owe their misfortune to this preventable disease. Treatment is, thorough cleansing with a quart of warm water daily, and a little silver nitrate. It was decided by the meeting to memorialize the various Boards of Health to place this malady among the notifiable diseases. In the discussion it was stated that formalin was very successful.

Dr. T. T. S. Harrison of Selkirk read a paper on

OBSERVATIONS ON THE HEREDITY OF CARCINOMA,

giving his experience in fifty-six years of practice.

One member had seen returning-cancer twenty-two years after operation.

SECOND DAY.

The first event was an explanation and illustration of X-ray apparatus and work, by DR. G. P. GIRDWOOD, in the chemical lecture-room of McGill College. Members were allowed to examine their hands, and other objects, in the fluoroscope. The fact is to be noted that the

first successful application of Röntgen skiagraphy in surgery in America was made with the instruments at McGill.

J. PRICE-BROWN discoursed on

CLERGYMAN'S SORE THROAT.

Many various conditions are given this name. There may be follicular pharyngitis, or chronic laryngitis. Nasal stenosis is often present, therefore always examine the nasal tract.

DR. GEORGE WILKINS of Montreal gave the

ADDRESS ON MEDICINE.

He referred to the great advances which had been made in medicine and surgery, and made his text "Modern Treatment as the Result of Experimentation." He paid a glowing tribute to the memory of Sir Joseph Lister, and stated that Jenner had laid the foundation of microbic pathology just one hundred years ago. The discovery of minute disease-producing organisms had furnished the link between science and therapeutics. It had upset the zymotic theory and revolutionized medicine. The introduction of serumtherapy marked a distinct epoch in the practice of medicine and gave to medicine something of the accuracy of the exact sciences.

After the morning session special cars carried the doctors to the Hotel Dieu. Here Senator SIR WILLIAM HINGSTON delivered an address on

DEBATABLE POINTS IN SURGERY,

giving his experience and preferences. He removes nose tumors by the mouth, aspirates for chest fluid, and uses trocar if pus has formed; prefers lithotrity to lithotomy, but met with a stone which resisted 250 pounds applied by lithotrite; would not operate by external opening for stricture. In cancer of breast, operate as early as possible and repeat; does not fear leaving a gland, as return is generally in the cicatrix or muscle; had operated in one case seven times and the patient was made comfortable, but died from an irrelevant disease. Sir William's work is modified by modern ideas, but he hesitates still to allow that theoretical Listerism is essential to good work. Cleanliness is very necessary, but antiseptics have no attraction for him. A tour through the wards was made. This fine hospital is under Les Religeuses, and evidences of ecclesiasticism, as crucifixes, religious paintings, candles, etc., are much *en evidence*. The wards have a medieval aspect, inasmuch as each bed is inclosed with a white curtain. An elegant repast was served.

At the afternoon session DR. JOHN STEWART of Halifax, gave the address on

SURGERY.

He apotheosized Lister and Listerism, pointing out the principles which had modified surgical practice the world over, and increased the sum of human happiness by the relief of conditions long held to be hopeless.

Honorable DR. D. MARCIL, Senator of Ste. Eustache, presented a paper in French on

THYROIDECTOMY.

This was the report of a successful case of removal of a one-sided goiter. The patient became myxedematous and was finally cured by thyroid extract. The doctor considered that in patients suffering from goiter, a peculiar diathesis existed and the gland was incapable of removing the morbid state. In the discussion, Dr. Hingston hinted that this idea would cause one to refuse to operate. Removal for cosmetic effect only is never justifiable.

DR. SHEPHERD had had several successful operations, and considered that only the cases in which the tumor could be shelled out were satisfactory for operation.

In the evening the annual banquet of the Association was held in the splendid rooms of the Windsor Hotel.

THIRD DAY.

DR. A. R. ROBINSON of New York spoke on

ETIOLOGY AND TREATMENT OF ACNE.

He believes common acne should be considered a local disease, though various inflammatory conditions of sebaceous glands and hair-follicles are included in the term; diagrammatic illustrations were given of comedones; the blackhead is rather due to chemical changes in the sebum than to foreign matter; staphylococci are generally present, therefore organisms become a factor; keratoses exist and present a strong argument for local treatment.

Treatment—Curette and empty follicles, hot water and green soap; no glycerin; acids or lemon-juice good for blackheads. Resorcin, sulphur, and salicylic acid for keratosis condition. Sublimate, if used, must be very weak. Pustules to be opened and disinfected. If boils, no matter how fat the patient, give cod-liver oil.

DR. SHEPHERD agreed as to the disease being local. He had found that the skin of patients in this country would not stand green soap.

PROFESSOR T. WESLEY MILLS and DR. S. KANE gave demonstrations of

BRAIN EXPERIMENTATION.

DR. MILLS considers the motor area almost *nil* in birds, but that it is of increasing value in the scale up to monkey and man, and centers are not equally active in all individuals. A pigeon was shown from which the entire cerebrum had been removed; it could flap the wings and fly a little. A kitten with areas for forelimbs and neck could wash its face in four days. A cat with right area removed seemed as well as ever. A rabbit, minus the motor area of both sides, was quite lively. A puppy, in same condition, scratches wound with both paws. Operations on dogs dangerous from hemorrhage.

DR. OSLER commented on the extreme importance of brain study in localizing abscess, tumors, etc.

DR. W. B. THISTLE put forth

A THEORY OF THE ELIMINATIVE TREATMENT OF TYPHOID FEVER.

It was an argument for the purgative treatment of typhoid, considering it due to toxins absorbed from the intestines. Different bacilli produce the symptoms, and they are but rarely found before nine days. Nature extrudes the toxins by the bile, the urine, the intestines, and the skin.

Treatment—Daily purges of calomel and magnesium sulphate, and salol as an internal disinfectant. Even in

comatose condition would purge, and has had good result.

DR. OSLER of Baltimore would not be rash enough to purge. He greatly feared cases where there is diarrhea.

Dr. MILLS believes that animals may digest normally without germs in the intestinal canal.

DR. G. LENOX CURTIS of New York gave a paper on

ORAL SURGERY.

He said that physicians and surgeons were generally unable or unwilling to deal with troubles in the mouth due to diseased or broken teeth, and proceeded to justify this rather strong statement by the relation of two cases which were unrelieved until they fell into the hands of an "oral" surgeon. In one case, a bad root caused the trouble; in the other, a chip of tooth.

DR. FRANK BULLER of Montreal gave demonstration of an

ARTIFICIAL NOSE-BRIDGE.

and related cases of foreign bodies in the eye in which the electromagnet had been used with success.

At the evening session,

DRS. WYATT JOHNSTON and GEORGE VILLENEUVE gave a study of

ENTOMOLOGY IN LEGAL MEDICINF.

The purpose was to establish rules to determine the length of time since death, and to compare the researches of Menien. The fauna on dead bodies agreed quite closely with that found by Menien in France, though in a different country. These gentlemen, having studied the subject in their duties as coroners' physicians, find that on a body dead three months, and exposed to the air, the animal found is the flesh-fly; from three to six months, acids develop in the flesh, and book-mites, cheese-mites, and species of dermestes may be found; from six to nine months, acari; nine to twelve months, mites. From one to three years there is but little left except ligaments, then tenebrio and attaglinus. By trial, it was found that dermestes would not lodge on a body under three months. Flies take a month to hatch out.

FOURTH DAY—MORNING SESSION.

The Committee on Intercolonial Registration reported as follows:

"Your committee beg leave to report that, having examined the present requirements of the licensing boards of the several provinces, with a view to obtaining by mutual concession a uniform standard of matriculation, education, and examination, wonld recommend the following:

"I. Matriculation.—The schedule of subjects shall comprise (1) English language, including grammar, composition, and writing from dictation; (2) arithmetic, including vulgar and decimal fractions, and the extraction of the square root; (3) algebra, to the end of the simple equations; (4) geometry, euclid, books 1, 2, and 3, with easy deductions; (5) Latin grammar, translation from specified authors, or of easy passages; (6) elementary mechanics of solids and fluids, comprising the elements of statics, dynamics, hydrostatics, and elementary chemistry; (7) history, England and Canada, with questions in modern geography; (8) and any one of the three following subjects: French, Greek, or German, the requirements being the same as in Latin.

"Fifty per cent. of the marks in every subject shall be necessary for a pass, and seventy-five per cent. for honors.

"In lieu of the above will be accepted a degree in Arts in any university in Her Majesty's Dominions, or from any college or university that may hereafter be recognized, but no matriculation in Arts in any university will be recognized.

"II. Professional Education. — The curriculum of professional studies shall begin after the passing of the matriculation examination, and shall comprise a graded course in the regular branches of four yearly sessions of not less than eight months of actual attendance on lectures in each year, the subjects to be anatomy, physiology, chemistry, materia medica, therapeutics, practical anatomy, histology, practical chemistry, pharmacy, surgery and clinical surgery, medicine and clinical medicine, including diseases of the eye, ear, throat, and nose, and mental diseases, obstetrics, diseases of women and children, medical jurisprudence, and tricology, hygiene, pathology, including bacteriology.

"That at least twenty-four months out of the graded four years, of eight months each, be required for attendance on hospital practice, to begin with the second year of study, That proof of attendance on not less than six cases of obstetrics be required.

"III. Examination—(*a*) All candidates for registration in the various provinces, in addition to having fulfilled the foregoing requirements, shall be required to undergo examination before examiners to be appointed in each of the provinces by their respective councils, or by means of assessors, as in the Province of Quebec, or by delegating their authority to one central body, as has been done in Manitoba. Each examination shall comprise all the subjects of professional study, shall be both written and oral, and fifty per cent. of the marks shall be required in every subject for a pass. (*b*) The committee make these resolutions merely as suggestions for the consideration of the councils of the several provinces as a mutual basis of agreement, and that each be requested to report thereon to the next annual meeting of the Association, and also to send one or more delegates to represent them at that meeting."

DR. RODDICK, on behalf of the Nominating Committee, made the following nominations, which were afterward unanimously approved by the Association: For president, Dr. V. H. Moore, Brockville. Vice-presidents: Prince Edward Island, James Conroy, Charlottetown; Nova Scotia, J. T. Black, Halifax; New Brunswick, T. Walker, St. John's; Quebec, J. M. Beausoliel, Montreal; Ontario, W. W. Dickson, Pembroke; Manitoba, R. S. Thornton, Deloraine; Northwest Territories, E. H. C. Rouleau, Calgary; British Columbia, Dr. Harrington, New Westminster. General secretary: F. N. G. Starr, Toronto (reëlected). General treasurer: H. B. Small, Ottawa (reëlected). Local secretaries: Prince Edward Island, H. D. Johnston; Nova Scotia, A. T. Mader, Halifax;

New Brunswick, G. A. B. Addy, St. John; Quebec, J. G. McCarthy, Montreal; Ontario, W. G. Anglin, Kingston; Manitoba, W. H. Smith; Northwest Territories, George Macdonald, Regina; British Columbia, A. Weld.

On the suggestion of the Nominating Committee, the city of Montreal was chosen as the next meeting place of the Association, it being thought advisable to meet there in 1897, since the British Medical Association will also assemble there during the summer of that year.

DR. J. F. W. ROSS of Toronto, gave the address on

OBSTETRICS.

He dwelt first on tumors complicating pregnancy. These are generally fibroid, and early ectrosmos is indicated. In large fibroids, celiotomy and incision of uterus. A case was related of rupture of uterus where, after cleansing, a rope of iodoform gauze was pulled through the tear down to the vagina; patient recovered. Cæsarean section and craniotomy were equally safe for mother, but not so for child.

Dr. CUSHING of Boston, said that in case of rupture, he would turn out uterus through vagina, and plug.

PROFESSOR J. C. WEBSTER of Edinburgh, spoke of

PESSARIES IN GYNECOLOGY.

There is no disease worthy of the designation anteversion. Many women have anteflexion without knowing it. Retroversion may occur without symptoms. If there are adhesions, you cannot replace by pessary, and tender ovaries will not bear pessaries. Occasionally, a Hodge, or Thomas, or Smith, or soft rubber, may be used. Practically, pessaries may be omitted, except cups for prolapse.

DR. A. LAPTHORN SMITH of Montreal, read a paper entitled:

ONE HUNDRED CASES OF RETROVERSION OF THE UTERUS TREATED BY VENTROFIXATION AND ALEXANDER'S OPERATION, WITH SUBSEQUENT RESULTS.

Of forty-two cases of Alexander's operation thirty-nine were successful; of sixty-six cases of ventrofixation sixty-three were satisfactory. Pregnancy occurs normally after this operation.

Dr. CUSHING said he had had more experience in removing pessaries than in putting them in place; does not approve of Alexander's operation. Dr. Gardner, of Montreal, finds but little use for pessaries; has abandoned Alexander's, but likes abdominal hysterorraphy.

Meeting adjourned to Royal Victoria Hospital.

DR. JAMES BELL showed some brain cases, now well, in one the temperosphenoidal lobe had been excavated, the result of ear trouble; a boy with thrombosis of sinus, the jugular was excised; a child of six years with a bullet in the brain, a photo. by X-rays showed the foreign body two inches from the forehead; two cases of sutured patellæ with perfect movement; four elbow cases; two cases of paralysis from too tight Esmarch—the solid round rubber has been abandoned on this account; floating kidney removed; a man with calculi in both kidneys; two cases of rib excision for empyema—in one sixty-five inches of rib structure had been removed; three cases of excised hips with good motion. Among the medical cases shown by DR. JAMES STEWART were six cases of thoracic aneurism; one with tabes; a case of multiple neuritis, ataxic type, without sensory disturbances; multiple neuritis with extreme wasting of legs in a girl, caused by (?) excessive medical administration of alcohol for a previous trouble; a case of cured Raynaud's disease, with loss of all the toes and two fingers.

DR. J. E. GRAHAM, of Toronto, read a paper on

THE INFLUENCE OF MITRAL LESIONS ON THE EXISTENCE OF PULMONARY CONSUMPTION.

Statistics were given showing the rareness of the combination, especially mitral stenosis. A suggestion made was that in heart lesions greater efforts of respiration were made, and this, acting as a kind of pulmonary gymnastics, led to better development of lung tissue, a bulwark against tuberculosis.

DR. OSLER had seen acute endocarditis in patients with tubercle occasionally. Case related in which diagnosis had been confidently made of heart lesion only at autopsy proved to be acute tuberculosis.

DR. BLACKADER, at Brampton Chest Hospital, had found the combination quite rare.

DR. W. TOBIN, of Halifax, presented a paper on

MILITIA MEDICAL REORGANIZATION.

This was the outline of a scheme which it was thought the Association might urge on the Minister of Militia, so that in case of being called out, the unreadiness would not be so great as at present. It was desired to make the service departmental rather than regimental.

DR. J. B. MCCONNELL reported a case of

TETANY FOLLOWING SCARLATINA.

Eleven days after onset of fever in a child tetany occurred in all four extremities, and lasted a week; child had had a previous attack.

DR. F. J. SHEPHERD, of Montreal, reported an

EXCISION OF A SCAPULA,

the first in Canada. The patient was a woman with a myelosarcomatous tumor which began two years previously with pain which was supposed to be rheumatism. Bone removed to neck, which was sawn through. Healing rapid and perfect movement of arms without drooping.

DR. H. L. REDDY presented the subject of

PUERPERAL INFECTION—TREATMENT BY MARMOREC'S ANTI-STREPTOCOCCIC SERUM.

Immediate improvement was manifest on use of injection, temperature fell three degrees in ten hours. Cure in twelve days.

DR. A. L. DEMARTIGNY, of Montreal, spoke of

ELECTRIC BATHS AND DYSPEPSIA.

He employs the Faradic current, and applies one electrode on the organ to be treated and the other in the water, and gets wonderfully good results in chronic dyspepsia.

DR. H. D. HAMILTON, of Montreal, reported a

NON-MALIGNANT TUMOR OF TONSIL,

and showed photo. It occurred in a man of twenty-two years, who was only aware of something wrong for two

weeks. It was two inches long and half an inch thick. Removed by electric snare, lymph adenoma.

The following papers were read by title: "Sinus Thrombosis Associated with Acute Suppurative Otitis Media in Scarlet Fever," Dr. J. W. Sterling, Montreal; "Cold Air in the Treatment of Pulmonary Tuberculosis," Dr. Edward Playter, Ottawa; "Early Atrophy of Muscles in Cerebral Disease," Dr. Frederick G. Finley, Montreal; "Treatment of Otitis Media Purulenta," Dr. A. Proudfoot, Montreal; "Technic of Vaginal Hysterectomy," Dr. L. Coyteux Prevost, Ottawa; "Actinomycosis," Dr. J. A. Springle, Montreal.

BRITISH MEDICAL ASSOCIATION.

Sixty-fourth Annual Meeting, July 28, 29, 30, 31, 1896.

(Concluded.)

SECTION ON PUBLIC MEDICINE AND HYGIENE.

G. V. POORE, M.D., F.R.C.P., Physician to University College Hospital, read a paper on

THE DISPOSAL OF DOMESTIC SLOP-WATER IN ISOLATED HOUSES.

He said that the slop-water of an isolated house must ultimately take the same course as the rain falling on the land upon which the house was built, that is, the line of natural drainage. Household slops consisted of bath-water, which was often almost clean; bedroom slops, composed of a mixture of soapy water and urine, and the waste of the kitchen and pantry sinks, which was apt to contain solid food, particles, and fat, and was very prone to become excessively foul. The flow from kitchen and pantry sinks, according to Notter and Firth, would average about four gallons per head per diem, and bedroom slops about five gallons per head per diem.

The points insisted upon were:

1. All waste-pipes should be well above ground-level.

2. All slop-water should run in open gutters, with perforated floors and good bottom-drainage, so that the water might soak away as it runs. Such gutters might with advantage be placed on low banks with sloping sides, and quick-growing shrubs, such as privet, should be planted alongside of them. These sucked up the moisture.

3. No stagnation must be permitted anywhere along a line of drainage, and, with the waste-pipes terminating in the open, no traps were necessary or advisable.

4. Slop-water should never be taken in pipes below the surface of the ground. Subsoil irrigation was a mistake.

5. The waste of the kitchen sink must be strained through a sink-basket and passed through a filter of rough stones before being allowed to flow to a gutter.

If there were sufficient ground to the house, he advocated the treatment of every variety of slops separately; and wherever the waste-waters of a house ran, there was always an increase of fertility and beauty.

DR. THRESH, Medical Officer of Health, Essex County Council, had carefully examined the sanitary arrangements referred to by Dr. Poore, and was much impressed with the apparent success. He dispensed with the sink-filter, and let the water pass through a short length of drain-pipe (to get the sewage clear of the house), and then discharge into the filtering or irrigation channel. The results had been very satisfactory.

DR. MAXWELL ROSS, Medical Officer of Health, County of Dumfries, stated that he also had had an opportunity of seeing Dr. Poore's methods in operation, and had since advocated them in his own district.

HENRY KENWOOD, M.B., D.P.H., F.C.S., spoke on

THE DISINFECTION OF ROOMS BY SULPHUROUS ACID GAS.

It is claimed, mainly on bacteriological grounds, that the process of disinfecting rooms by sulphurous acid gas is inefficient; that the SO_2 generated by the combustion of one pound of sulphur in one thousand cubic feet of space is not sufficient to kill the specific organisms of infectious disease, more especially when no measures are taken to charge the atmosphere with moisture.

He had searched most carefully for the evidence furnished during the year (1895) in a population of 254,000 people, from six sanitary areas in and around London, sulphurous acid being, in every case, the disinfectant employed. There were, in all, 1330 premises disinfected by the local authorities, 409 in respect of diphtheria and 921 in respect of scarlet fever, and 55 cases (4.1 per cent.) of either scarlet fever or diphtheria occurred on the same premises within fourteen days of their fumigation.

But the origin of much of this 4.1 per cent. may be attributed to: Infection from the preceding case; persistence of the same source of infection which accounted for the disease in the original case; the contraction of the disease away from the premises in question within the period above specified; and even the return of clothes and bedding from the disinfecting station.

Sulphurous acid is used to disinfect the walls, ceiling, floor, and bare surfaces in a room. Bedding, clothing, carpets, curtains, etc., should be removed for steam disinfection.

The method consists of two stages: (1) The charging of the atmosphere for from six to eight hours with about one per cent. of sulphurous anhydrid gas, by means of burning one pound of sulphur to every thousand feet of space in the room; (2) the thorough aeration of the room.

The second stage is an essential part of the process, in order to rid the room of SO_2. By some it has been argued that it is this thorough aeration that does the good. It is easily demonstrable that the diphtheria bacillus would be at most attenuated by such aeration, and not killed.

Mr. Walter D. Severn collaborated with him in a few bacteriological experiments, principally directed to the Klebs-Loeffler bacillus of diphtheria, for the following reasons: It is concerned in the production of one of the diseases in which the disinfecting power of SO_2 is most commonly relied upon. It is easily cultivated, its cultures are unmistakeable, and it possesses a rapidity of growth over accidental impurities in the culture media employed.

The room employed was in his own house. It was nearly square, 8 feet 8 inches in height, and had a capacity of 2004 cubic feet. Before each experiment the room was left at rest for some time, the inoculated swabs, etc., were then placed in position, and the room was treated by the man who does the disinfecting work of the parish

precisely as if there had been a case of infectious illness in it. Each experiment comprised six different tests applied at the same time at three different levels in the room —two at the level of the floor, two on a sideboard 3 feet 8 inches from the floor, and two on a bracket 6 feet 6 inches from the floor—to determine the effect produced by from six to eight hours' exposure to an atmosphere containing SO_2 not exceeding one per cent.

In the first series all three swabs and all three lints were sterile.

In the second series a serum-tube inoculated from one swab showed a late (inhibited) growth of the Klebs-Loeffler bacillus after three days, but no growth was obtained from the other two swabs or from the three lints.

In the third and fourth series no growth of *B. diphtheriæ* was obtained from any of the swabs or lints.

In Series 1 and 2 one tin of liquefied SO_2, alleged to contain twenty ounces, was employed in each case.

In Series 3 two such tubes were employed.

In Series 4 two sulphur candles were burned, each containing one pound of sulphur.

Where the diphtheria bacillus was not killed, it was very markedly inhibited, even where the SO_2 did not much exceed one-fourth per cent., and the bacillus was killed where the SO_2 exceeded one-half per cent., the above figures having sole reference to the SO_2 in the air in the center of the room at a height of four feet, and after the lapse of four hours.

SIR CHARLES CAMERON had, twenty-four years ago, made experiments on the action of dry sulphur dioxid and chlorin on vaccine lymph, and found that they only produced effects when used in large quantities; but solutions, even when used in very small quantity, destroyed the virus of vaccine. Lately he had in many cases used the spraying method, for the sake of the delay it saved.

DR. SYMONS, Medical Officer of Health, Bath, desired to know if Dr. Kenwood had met with any instance of injury resulting to subsequent occupants of the rooms. Compressed gas has many advantages over burning sulphur; but even this agent may be useless in the hands of a careless workman who overlooks any outlet. The mercuric-chlorid spray solution had not this disadvantage, and the room could be immediately occupied.

DR. GROVES, Carisbrooke, was glad this subject had been dealt with, owing to the uncertainty caused by recent criticism. If used properly and in sufficient quantity (1½ pound), sulphuric-acid gas was quite efficient. For twelve years he had not known of a recurrent case in his own district after the use of burning sulphur.

DR. F. J. ALLAN, Medical Officer of Health, Strand, was inclined to think that the influence of sulphurous-acid gas had been underestimated, especially when in the presence of moisture. They had not taken into consideration the oxidation and deoxidation which occurs.

DR. KENWOOD, in reply, stated that he knew of no cases of direct injury resulting to persons entering the room after the SO_2 had been liberated. As to Dr. Symons' question whether the control-swabs were subjected to similar conditions of light, etc., as those exposed about the room during disinfection, every care was taken to make the conditions as similar as possible. With regard to Sir C. Cameron's question whether he considered the tubes of liquefied gas more or less efficient than burning sulphur, he believed that one pound of sulphur, when completely burned, gave more sulphuric-anhydrid gas to the atmosphere than twenty ounces of liquefied sulphurous-acid gas, and that this gas was more evenly distributed throughout the room.

SIR CHARLES A. CAMERON, M.R.C.P.I., Medical Officer of Health, Dublin, reported

AN OUTBREAK OF ENTERIC FEVER DUE TO INFECTED MILK.

In May, 1896, the two daughters of the owner of a milk-shop in Meath street were ill with enteric fever. He visited the place and had the children at once removed and the milk in the shop destroyed. Fourteen persons who had been supplied with milk from this dairy were suffering from enteric fever. The cows which supplied the milk were out on pasture. The water in the dairy was pure. The milk apparently became infected from absorbing exhalations from the dejecta of the patients while being carried down the stairs to be thrown into the water-closet or ashpit. He placed some enteric dejections close to a vessel of milk, and in ten minutes found that the milk had become infected, as proved by subsequent cultivations.

JOHN C. THRESH, M.D., D.Sc., Medical Officer of Health to the County of Essex, introduced the discussion on

DIPHTHERIA IN TOWN AND COUNTRY.

He said that the county of Essex had at the present time a higher mortality from diphtheria than any other similar area in the United Kingdom, and certain districts within the county had higher rates than prevail even within the metropolitan area.

He presented statistics which showed a continuous increase, both in the urban and rural districts. Judged either by the case-rate or death-rate, diphtheria was shown to be about fifty per cent. more prevalent in the towns than in the country districts.

With reference to elevation, he found that epidemics occurred as frequently in parishes in hilly districts as in those in the valleys and near the marshes, and on the marshes dotted with farms and laborers' cottages a case of diphtheria is of exceedingly rare occurrence.

The degree of overcrowding and the diphtheria case-rate in tenements of four rooms and under exhibited a close correspondence.

The quality of the water supplies, presence or absence of drainage, the character of the soil and subsoil, seem of of themselves of trifling importance in affecting the prevalence of the disease. Epidemics may occur in the most sanitary, as well as in the most unsanitary, areas. The decreased prevalence of diphtheria in the urban rural districts in July, he suggested, was because that month exhibited fewer variations to cause cold and affections of the throat. In October, when the sudden increase occurs, the weather is more variable, there is a very marked fall in the average temperature and an increase in the relative humidity of the atmosphere—all conditions favorable to the production of the disease.

Investigations of outbreaks, in rural districts especially, give the impression that the rainfall, the fluctuations of the ground water, the temperature of the air and soil, the humidity of the atmosphere, etc., are only of importance in so far as they tend to cause congestion of the mucous membrane of the fauces and render persons so affected liable to be successfully attacked by the diphtheria bacillus should it by any means gain access thereto. To explain the innumerable instances in which an excessive prevalence of sore throat has preceded an outbreak of diphtheria, we must assume either that there has been a "progressive increase of infectivity" or that the earlier cases were not diphtheritic, and that later cases only became so upon the introduction of the specific organism. He had frequently failed to obtain the bacillus from such throats, and had found them, or organisms indistinguishable therefrom, on apparently healthy throats, and consequently his faith was shaken in the "progressive increase of infectivity" theory.

He urged that all medical officers, especially those in rural districts, should give more attention to isolated outbreaks, as they are far more worthy of study and far more likely to lead to valuable etiological conclusions than the investigation of extensive epidemics.

F. A. DIXEY, M.A., M.D., Fellow of Wadham College, Oxford, presented

VITAL STATISTICS OF DIPHTHERIA IN LONDON.

He concluded by a review of the effect of the antitoxin treatment. Comparing the average weekly number of deaths for the last five years, we find that after rising from 26.2 in 1891 to 36.2 in 1892 and 62.8 in 1893, it fell to 51.4 in 1894 and 44.5 in 1895. It is true that the opening months of 1895 promised a greater diminution than that exhibited by the figures for the whole year, and that the intensity of the rise last autumn seems to show that some other factor than the antitoxin treatment must have been concerned in the diminished mortality at the end of 1894; but notwithstanding these facts, which are freely admitted, it would seem that the general run, even of these figures, suggests a conclusion favorable to the efficacy of the treatment. This conclusion becomes strengthened if the case-mortality, or relation of deaths to notifications, is considered. Under this head the main facts are as follows: The number of cases notified during 1893 was 13,694; of deaths during the same year, 3624, giving a case-mortality of 23.8 per cent. In 1894 the corresponding figures were 11,190 and 2674; the case-mortality stood, therefore, at 23.9. In 1895, however, while the notifications rose to 11,229, the fatal cases fell to 2289, and the case-mortality was therefore only 20.4 per cent. —the lowest rate for a whole year yet recorded. The numbers for the first half of the present year are respectively 6193 cases notified and 1239 deaths, which work out to a case-mortality of 20.2 per cent. In view of the fact that, quite irrespective of the number of cases, the case-mortality of the last half of the year is invariably below that of the first, it may fairly be anticipated that by the end of 1896 the year's case-mortality will, for the first time on record, have sunk below 20 per cent. This diminution in case-mortality he could attribute to no other cause than the treatment by antitoxin.

DR. COOPER-PATTIN, Medical Officer of Health, City of Morwich, had noted the association (in his district) of diphtheria notifications with the humidity of the atmosphere. In twenty-five per cent. of the houses infected he had found evidence of persistent dampness of the walls, floors, etc. With regard to the "progressive intensity" theory, he had noticed in seven cases occurring in one house retrogression of intensity of the attack. He believed that bad sanitary conditions could be lived under, even for years, and then the accidental introduction of some new factor led to the occurrence of the disease. This new factor was to be found in the disturbance of excrement during scavenging.

PROFESSOR TREVELYAN believed that until something definite was known about the behavior of the bacillus outside the body, it would seem almost impossible to study completely the prevalence and spread of the disease.

DR. ALLAN, Medical Officer of Health, Strand District, thought that a number of cases notified as diphtheria were in reality scarlet fever; they certainly accompanied one another in a striking manner. He agreed with Dr. Thresh that unsanitary conditions act solely as predisposing influences.

GEORGE LANE MULLINS, M.A., M.D., Trinity College, Dublin, Physician to the Hospice for the Dying, Sydney, contributed a paper on

NEW SOUTH WALES AS A HEALTH RESORT FOR BRITISH CONSUMPTIVES.

GORDON SHARP, M.B.Edin., of Leeds, spoke on

THE SOIL IN RELATION TO DIPHTHERIA AND ITS ORGANISM.

His conclusions were:

1. Diphtheria would appear to be endemic in certain districts. Soils organically laden are dangerous, but much may depend on the nature of the subsoil. Where the subsoil is porous, a neighborhood may be free; where the subsoil is impervious, the surface, at certain seasons of the year, may be a favorable breeding-ground.

2. Soils which would otherwise be sources of the spread of diphtheria are rendered innocuous by deep drainage.

3. The presence of a large quantity of air in the surface soil appears to be salutary, and the contrary holds.

The close connection between enteric fever, scarlatina, and diphtheria has often been remarked, and Bond has especially called attention to the close relationship between scarlatina and diphtheria, and formerly the connection seems to have been even more marked. Thorne has called attention to the fact that as authorities have improved their water supply, enteric fever has declined in frequency, while under the same conditions and with improved sewerage systems diphtheria has increased. Immersion in water for a short time seems fatal to the microbe of diphtheria, while the contrary holds with regard to the organism of enteric fever; both seem to live in sewage. A moist, rather than a water-laden, soil seems to be the home of the organism of diphtheria.

ANNOUNCEMENT.

TRANSPORTATION ARRANGEMENTS FOR THE MEXICAN MEETING OF THE PAN-AMERICAN MEDICAL CONGRESS.

DR. H. L. E. JOHNSON, 1400 L street, N. W., Washington, D.C., has been elected chairman of the Special Committee on Transportation. All communications relative to rates, reservation in the special trains, etc., should be addressed to him. A rate of one fare for the round trip has been secured between St. Louis, New Orleans, and other trans-Mississippi points and the City of Mexico. It is confidently expected that this rate will be extended over the entire territory of the United States. Arrangements are in progress for a splendidly equipped special train of sleeping and observation cars, with first-class dining-car service. Dr. Johnson will presently be in position to announce a rate, which will include railroad fare, sleeping- and dining-car service, both ways, and in the City of Mexico, and covering the expense of various side trips to the most important historic points in the Republic.—Charles A. L. Reed, Secretary International Executive Committee.

SELECTION.

ANOTHER GLOUCESTER OBJECT-LESSON.

IN the daily press of last Saturday, which contained copious extracts from the report of the majority of the Vaccination Commission, there also appeared an item of news of singular significance in face of the conclusions at which the Commission is said to have arrived. This was a statement to the effect that on the previous day at Gloucester a public demonstration had been held by anti-vaccinationists to welcome the release from prison of a defaulter under the Acts. It is not, perhaps, so much a matter of surprise that this should happen in Gloucester, where, after a suspension of ten years, the law is now being enforced, for during this period the anti-vaccination crusade has been, as we all know, most vigorously conducted, and there must be many in that city to whom compulsory vaccination must seem a thing to be resisted to the death. But what is indeed surprising, nay more, profoundly disheartening, is the fact that those people who have suffered so much from the disease, which vaccination prevents and mitigates, should nevertheless seize the first opportunity to show that this bitter lesson has been taught them in vain. We are told that the defaulter in question was in the service of the Midland Railway Company, and that the crowd which accompanied him in his progress through the streets contained many of the employees of this company in their uniform. What makes the affair more shameful still is the notorious fact that in this recent epidemic, of the two great railway companies whose lines converge at Gloucester, the servants of the Great Western Railway Company hardly suffered at all, whereas the disease was rife among the Midland men, the fact being that the former company required their men to be re-vaccinated, while the latter declined to put any pressure upon them at all. Let us hope, for the sake of human nature, as well as our belief in the intelligence of such men, that none of those who took part in this demonstration (which, of course, may have been largely based on the personal popularity of the offender) had suffered in their own families from the visitation of smallpox. It would, indeed, be incredible if any man, whose home had been recently decimated by reason of his own perversity in failing to secure for his children protection from the plague which smote them down, could be so wilfully and grossly blinded by unreason as to continue in the delusion he hitherto held. Have the wives of such men and the mothers of those dead children no voice in the matter; and is there no sense of shame among the people of Gloucester to permit such an exhibition of heartlessness and ignorance to be made in their midst? It is said that Gloucester has been converted by its recent object-lesson, but we await for some overt sign of this "conversion" which shall prove to the world that the vast majority of its citizens no longer have part or lot with those whose baseless propaganda have been the direct cause of so much misery and death.—*London Lancet.*

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE FIFTEEN DAYS ENDED AUGUST 15, 1896.

HUTTON, W. H. H., Surgeon. Granted leave of absence for twenty days from August 25, 1896, August 13, 1896.

SAWTELLE, H. W., Surgeon. Granted leave of absence for thirty days from August 25, 1896, August 13, 1896.

BANKS, C. E., Surgeon. To assume temporary command of the Service at Vineyard Haven, Mass., for thirty days, August 13, 1896.

BROOKS, S. D., Passed Assistant Surgeon. To assume temporary command of the Service at Cleveland, Ohio, August 8, 1896.

WOODWARD, R. M., Passed Assistant Surgeon. Granted leave of absence for thirty days from August 13, 1896, August 11, 1896.

GREENE, JOS. B., Assistant Surgeon. Granted leave of absence for twenty-three days from September 14, 1896, August 13, 1896.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 8, 1896.

August 4.—Passed assistant surgeon G. H. BARBER, detached from the "New York," ordered home and granted two months' leave.

Passed assistant surgeon V. C. B. MEANS, detached from the "Maine," and ordered to the "New York."

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 15, 1896.

August 9.—Assistant Surgeon M. K. JOHNSON detached from the U.S.S. "New York" and to the Coast Survey Str. "Bache."

August 12.—Passed Assistant Surgeon G. A. LUNG ordered to the Receiving Ship "Vermont."

August 12.—Passed Assistant Surgeon E. R. STITT detached from the Receiving Ship "Vermont" and ordered home on waiting orders.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 4, 1896, TO AUGUST 17, 1896.

Leave of absence for one month is granted Captain William. D. Crosby, Assistant Surgeon, Fort Missoula, Mont.

The leave of absence granted Major Henry McElderry, Surgeon, Fort Robinson, Neb., is extended two months.

The extension of leave of absence on account of disability granted Major Clarence Ewen, Surgeon, is further extended one month on account of disability.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXIX. NEW YORK, SATURDAY, SEPTEMBER 12, 1896. NO. 11.

ORIGINAL ARTICLES.

THE CLINICAL USES OF THE PREPARATIONS FROM THE THYROID GLAND, PITUITARY BODY, SUPRARENAL CAPSULES, AND BONE-MARROW.[1]

BY RICHARD C. CABOT, M.D.,
OF BOSTON.

To cover the ground with reasonable thoroughness I have had to limit myself in two directions. First, I have kept strictly to the title of my paper and studied only the *clinical uses* of these preparations and not the theory of their nature, the modes of their preparation or action, nor the history of their introduction into medicine. Secondly, I have thought it best to say nothing at all of the uses of the preparations of the thyroid gland in myxedema, sporadic and endemic cretinism, and cachexia strumipriva. The usefulness of thyroid extract in these conditions is now so well established that any discussion of it would be tedious. Therefore, in speaking of the thyroid extract I shall confine myself to its uses in conditions other than those just mentioned.

THYROID EXTRACT.

Besides myxedema, cretinism, and the cachexia following thyroid extirpation, there is a long list of diseased conditions in which thyroid extract has been used, the most important of which are: (1) Simple goiter. (2) Exophthalmic goiter, or Graves' disease. (3) Obesity. (4) Psoriasis and other cutaneous diseases, including alopecia. (5) Tetany. (6) Insanity and various psychoses. (7) Retarded development in children. (8) Chlorosis. The thread that binds all these apparently heterogeneous conditions together is the fact that they all are, or may be, associated with myxedema, and when so associated have been cured or ameliorated by the thyroid treatment. Thus, some myxedematous patients are goitrous, many are fat and suffer from various cutaneous disorders; mental troubles are a very frequent symptom, and retarded development not uncommon. Many myxedematous patients get very anemic, and some, especially those whose myxedema is due to removal of the thyroid, show the spasms of tetany. Hence, it has occurred to physicians to use the thyroid treatment in each of these conditions when occurring without myxedema.

Further, the thyroid preparations have been used in rickets probably from a general sense of its value in diseases of nutrition, and perhaps the same idea may have led to its use in diabetes and gout. It has been used in fibroid tumors of the uterus, and for hypertrophied scars—its marked powers of tissue metamorphosis probably recommending it. Favorable reports of its use in lupus led to its use in phthisis, and, finally, syphilis, cancer, and leprosy, have been experimented on. It is said to be good for piles.

I will take up these various uses of the thyroid extract in what seems to be the order of their importance.

THYROID EXTRACT FOR SIMPLE GOITER.

Relief is sought in these cases either on account of the disfigurement and inconvenience of the tumor, or because of the pressure symptoms which it causes. Without treatment, tracheotomy is sometimes necessary to relieve the distress of breathing.

Out of a total of 322 published cases, 279, or eighty-seven per cent., are set down as improved, and only 43 as not improved (see table). These statistics are large enough to be convincing, I think, of the great value of thyroid extract in simple parenchymatous goiter. There have been, so far as I can ascertain, no wholly unfavorable reports—none where marked improvement has not appeared in a majority of all cases in which any one observer has tried it. Those who have tried the remedy, in large numbers of cases, agree that it is most effective in goiters that are of recent appearance and of moderate size, and especially in those occurring in young people.[1]

Failures are mostly in cystic or colloid goiter, and in middle-aged people who have had the tumor a long time. It seems safe to say that every parenchymatous goiter of recent appearance in a young person can be considerably diminished by thyroid feeding. It is uncommon to see the tumor wholly disappear, only about ten per cent. of the cases having so resulted, but often there remain only a few hard nodules not previously felt, which can be easily dissected out.

[1] Read before the Massachusetts State Medical Society, June 9, 1896.

[1] The younger the better. Thomas reports splendid results in sucklings with congenital goiter.

THYROID FEEDING IN GOITER.

TABLE NO. I.

Author.	No. of Cases.	Cured.	Improved.	Not Improved.	Remarks.
Bruns	60	14	29	17	Used the raw gland itself. "Thyroidism" in 1 case only. 3 relapsed after treatment omitted. Failures=(a) cystic or colloid goiters; (b) adult patients with tumors of long standing.
Kocher	7	0	5	2	The failures were a goiter and a colloid tumor.
Séné	1	0	1	0	
Alexjew	2	1	1	0	
Epelbaum	1	0	1	0	
Ingals & Ohls [1]	50	2	36	11	1 case not heard from. 2 of those not improved were under treatment less than a week. Cystic tumors were not excluded.
Knopfelmacher	22	(12 [2])	5	5	The 5 obstinate cases were also unaffected by the iodin treatment, by ointment, and internally.
Marie	1	0	1	0	Showed diminution in size within 5 days.
Reinhold	12	0	12	0	Insane patients—7 lost an average of 4 lbs. weight in 6 weeks. 2 gained weight (3-9 lbs.). No change in mental symptoms.
Angerer	78	0	72	6	Those not improved gave up treatment on account of "thyroidism;" most lost weight (6 lbs. in 5 weeks'-average), but gained it back later. 2 relapses in 5 and 7 months after omission of treatment. Prefers the raw gland.
Stabel	60	4	56	0	26 cases on raw gland did much better than 34 on tablets; no "thyroidism."
Ewald	19	0	19	0	Used English tablets and finds them much better than German.
Putnam	3	0	?	1	2 not heard from.
Thomas	?	?	all	0	"Splendid results." All in young infants.
Hennig	2	0	1	1	Using "thyrojodin."
Eschler	"many"	"many"	?	?	Does best in young people.
Sanger	1	0	1	0	

Some of the cases show distinct diminution in the size of the goiter after four or five days' treatment, and in several the tumor was entirely gone within a month. After from six to ten weeks' treatment the diminution has usually reached its limit, but some continue to improve for a longer period, and occasionally it is six weeks before any improvement begins.

As most of the statistics are very recent, our knowledge as to the permanency of the cures is obviously very limited. Nine months after the cessation of treatment many of the cases have shown no relapse. On the other hand, Bruns finds three-fourths of his sixty cases begin to relapse three months after cessation of treatment. The statements of observers are not sufficiently full on this point in most cases, and we cannot say at present how frequently the marked improvements above recorded are destined to be permanent, and whether, as in myxedema, we must maintain the thyroid treatment through life to prevent relapse. Those cases which disappear most rapidly under thyroid treatment have shown, according to Stabel, the greatest tendency to relapse. Slight loss of weight during the treatment is the rule, averaging five or six pounds in Angerer's 78 cases. Severe toxic symptoms are rare and can be prevented by care (*Vide infra*).

[1] Including cases reported in letters to the author.
[2] Nearly.

THYROID TREATMENT IN OBESITY.

The vast majority of observers are agreed that most obese persons, and many who are not so, lose weight rapidly during the first week of treatment with thyroid extract, the diet being unrestricted. We can tell to a certain extent what type of obesity is most likely to be benefited. Leichtenstern, Buquin, Kraus, and other observers have noticed that in young, robust, and vigorous, but obese persons, the treatment is not effective. It is especially successful where obesity is associated with pallor, and flabby, doughy tissues, and as such a condition is commoner in women, the remedy more often works well in women than in men. The loss of weight is most rapid during the first week of treatment, but continues more slowly for months in some cases. Among the most striking cases are those of J. J. Putnam, who was the first, so far as I can ascertain, to use thyroid extract in simple obesity. One of his patients lost forty-seven pounds under thyroid treatment. Ratjen reports a loss of fifty-seven pounds in three months' treatment. Rendu's case lost sixty-six pounds in two months with no relapse up to date (one year). A loss of a pound a day for the first week is not at all uncommon.

In most cases this loss of weight represents not simply a loss of fat (and water) from the tissues, but a drain on the lean as well. The excreta show that an increased amount of albuminoid matter is

being burnt up in the body, so that muscle as well as fat is lost. V. Noorden says that thyroid extract is the only known drug that increases the process of oxidation in the body without muscular or glandular exercise. He compares it to the blast from "a pair of bellows rousing the smoldering fire of metabolism to fiercer flames." But as regards the albuminoids of the body, this is just what we want to avoid in our treatment of obesity, and, in fact, it can be avoided if a diet is so arranged that the loss of albuminoids is compensated by an increase in the proteid elements of the diet.

The majority of observers agree that the weight is soon regained after the remedy is left off, unless exercise or careful dieting prevents it. This relapse does not always occur, and is often delayed some weeks, or even months, after the remedy is omitted, but in a larger number of cases the weight begins to increase again very quickly, and not infrequently reaches its former figure within a month. Cases are recorded where patients have actually gained weight during the use of the remedy, but this is very rare.

At the Congress for Internal Medicine, held at Wiesbaden just two months ago to-day, Ewald sums up a discussion on this topic with the conclusion that we have in thyroid feeding a precious remedy in cases of obesity, and one whose ill effects can all be avoided. He recommends that we should never give this treatment to any patient whom we cannot watch closely, for the dangers inherent in its use are considerable.[2] In some of the cases he says the remedy entirely fails, the tendency of the organism to conserve its fat being very strong. He compares such cases to those of pernicious anemia where the preservation of the fat layer up to death is so striking.

THYROID TREATMENT OF OBESITY.

TABLE NO. II.

Author.	No. of Cases.	Loss of Weight.	Duration Treatment	Not Improved	Relapsed.	Remarks.
Leichtenstern and Wendelstadt	27	3-19 lbs.	4-6 weeks.	2	?	Anemic, flabby cases do best.
Rendu	2	66 lbs. in 1, "marvelous" in the other.	2 months.	0	none so far 1 year.	Used tablets of dried extract.
Dennig	5	6 lbs. av.	10-27 days.	1	1	Some show increase of albumin excretion, others do not.
Buquin	3					
——[1]	3	9 lbs ; 16 lbs ; ? lbs.	3 weeks.			
V. Noorden	17	"Considerable."	?	?	"Most"	Finds it useless unless supplemented by diet, but helps somewhat where diet alone fails.
Ingals	2	5 lbs. in 1.	?	1	?	1 case gained 5 lbs. under treatment.
MacKenzie	1	8½ lbs.	1 month.	0	Yes.	Gained back 5 lbs. while still taking thyroid
Smith	1	"Considerable."	?	0	?	
Schlesinger	1	"Very successful."				Tablets of beef thyroid had no effect.
Jerzykowski	10	"Considerable."	?	?	?	Effective only when combined with diet. Used Merck's tablets.
Putnam	6	40 lbs. in 1 ; 47 lbs. in 1.			Yes.	Relapsed when thyroid was omitted. Other cases lost no weight.
Bleibtreu	1	6½ lbs.	?	0	?	Lost albuminoids in spite of increased protein diet.
Meltzer	1	?	?	0	?	Began to improve in 24 hours.
Buschan	1	"much"	?	0	?	
Ratjen	1	57 lbs.	3 months.	0	?	
Barron	5	1 lost 28 lbs., others less.	6 weeks.	0	?	
Becker	2	7 and 10 lbs.	1 week.		Yes.	
Bournville	6	4, 5, 6, 8 and 12 lbs.	8-10 weeks	1	Yes.	Idiotic children all relapsed, some during treatment.
Davies	1	"Considerable."	?	0	?	In this case diet alone was useless, but with thyroids too, was very efficacious.
Williams	7	"Considerable," 36 in 1	?	1	0	Acne rosacea in 2: markedly improved.
Baldwin	3	1 lost 40 ; 1 lost 10 ; 1 lost several lbs.	?	0	3	Weight regained because active exercise not kept up after stopping thyroid extract
Grawitz	2	6 lbs.	1-3 weeks	0	?	Using "thyrojodin."
Hennig	24	2 ten lbs. per week.	?	0	?	Using "thyrojodin" 1 lost 20 lbs. in 23 days.
Ewald	11	8 ten lbs.	6 weeks.	1	"Most"	Using "thyrojodin."
Eulenburg	1	17	?	?	?	
Magnus-Lewy	1	8 lbs.				
Total	145					

[1] Letter to *Munich. med. Woch.*, April 23, 1895.

[2] The danger signals will be briefly considered later on.

Drs. H. C. Baldwin and Harold Williams of Boston, have been good enough to let me mention the results of their experience in the thyroid treatment of obesity. Dr. Baldwin's three cases showed marked loss of weight, but relapsed because exercise was not kept up after the remedy was omitted. Some of Dr. Williams' seven cases have not relapsed and have been in all respects successful. In two an associated acne rosacea improved much during the treatment.

Out of a total of 145 cases which I have been been able to collect, all but 6 got thinner under the treatment, so that, except for the question of relapse, the treatment was successful in over ninety-six per cent. of the recorded cases. How often and for how long relapse can be prevented, either by continuing the thyroid treatment, by exercise, by diet, or by a combination of these measures, we are not yet in a position to know.

THYROID FEEDING IN SKIN DISEASES.

Here the results have been markedly poorer than in goiter and obesity. The remedy has been tried to a limited extent in a variety of diseases affecting the skin but especially in psoriasis. Here, out of 153 cases, only 62 improved during treatment, and of these only 43 had thyroid treatment without local remedies as well, so that only about one-fourth of the cases can be said to be really improved by the thyroid. Further, as the records of these cases are all very recent, and as very little is said as to the presence or absence of relapses, we may well hesitate to believe that the results are really due to the treatment and not to one of the spontaneous ameliorations so common in the course of the disease. Those most sanguine as to the merits of thyroid extract for psoriasis admit that there are many cases in which it has no effect, and some (about one-sixth) who are made worse by it. Byrom Bramwell thinks it a specific for certain types of the disease, but he has never attempted to point out any means of knowing beforehand whether a given case will be made better or worse by it. Radcliffe Crocker of London, considers it very valuable in the "right cases." Crocker says that it "should never be given during the increasing stage of the disease," as sometimes scores of new spots rapidly develop under it. He finds it "very capricious in its ac-

Thyroid Treatment of Psoriasis.

Table III.

Author.	No. of Cases.	Improved.	Not Improved	Worse.	Relapse.	Remarks.
Abraham	65	18 (11 had local treatment, too).	16	15	?	In 11 treatment had not continued long enough to judge of its results.
Thibierge	11	8	3	0	?	Average loss of weight 12 lbs in 6 weeks. Those who improved had local treatment too.
Crary	9	2	7	0	?	Noticed peculiar "meaty" odor to skin.
Busch	24	18	6	0	?	11 "cured."
Bramwell	6	3	3		0	1 very stubborn case cured in few weeks without local treatment; 2 are well (6 months, no relapse).
Squire	2	0	2			
Dill	4	3	0	1		1 "cured."

tion, failing in one attack after it has succeeded in a previous one. In children and sound young people it is often effectual." Thibierge believes in its utility but thinks it should be reserved for refractory cases where other remedies fail. It is in such cases that the treatment by thyroid feeding has scored its most striking successes. Age and sex seem to make little difference (Abraham), although Eschle thought fresh cases in young persons were more amenable to this treatment.

In eczema, of a total of 22 cases reported, 9 are set down as "cured," 3 as improved, 2 as unimproved, 1 as worse, and in 7 the result is not clearly stated. Out of 7 cases of ichthyosis, only 1 is called "cured," another was "cured but relapsed when treatment stopped," 4 are improved, and 1 unimproved. Of 4 cases of xerodema, 1 showed improvement; the others none. Two cases of sclerodema are reported; 1 was improved and 1 was "cured." Three cases of acne rosacea gave 2 improved—Dr. Harold Williams' cases—one not improved. Success is mentioned in single cases of adenoma sebaceum, pityriasis rubra, and exfoliative dermatitis, and failure in a case of vitiligo. Four chronic leg ulcers exhibited no improvement. Two cases of alopecia are reported as improved, but MacKenzie claims to have tried it thoroughly and found it useless in this disease. The use of thyroid feeding in lupus seems to have been successful in the hands of Byrom Bramwell. Busch and Abraham reported 12 cases, all more or less improved. In 5 of these, however, local treatment was given at the same time. No complete cures are reported.

THYROID TREATMENT IN PHTHISIS.

This apparent success with cutaneous tuberculosis induced Morin of Neuchatel to try the remedy in pulmonary tuberculosis, and he has been followed by Kraus in Germany, and by T. Smith in England. All of these observers report generally favorable results but nothing very definite or permanent. Morin believes the goiter and tuberculosis are antagonistic. He noted the frequency of atrophied thyroid in phthisis, and out of 71 cases of myxedema found 20 tubercular. Girard of Berne, noted that in the districts where goiters prevail, phthisis is more than twice as common in the non-goitrous as in those with goiters. It is a popular belief in these regions, he says, that goiter and tuberculosis are antagonistic. Morin also reports a phthisical patient who improved markedly after acquiring goiter. In one very tubercular family he found every member phthisical except those whose thyroid was enlarged.

Kraus did not find that phthisical patients lost any weight under thyroid treatment, in fact, notes a gain in weight in one case, but he found no change in the signs in the lung.

During the past ten days I have been giving thyroid extract to six phthisical patients. No particular change has been noted.

THYROID TREATMENT IN SYPHILIS.

This remedy has also been tried in syphilis. Six favorable cases are reported, 5 of them said to be very severe, while in 11 cases no improvement has been seen.

MISCELLANEOUS USES OF THYROID FEEDING.

(1) The first condition I shall mention under this heading is an interesting case of hypertrophied scar, reported by Dr. J. W. White, in which, during thyroid feeding, a large unsightly mass, resembling keloid, shriveled away so as to leave only a linear scar. Dr. White had previously tried various local treatments with no success. (2) The unsuccessful use of thyroid feeding in cancer needs no further comment. (3) At the Wiesbaden Congress of last April, above-mentioned, where the whole subject of thyroid feeding was discussed, favorable results were reported in a great variety of conditions; for example, in chlorosis, rickets, gout, and diabetes. The cases are too few and the reports too meager for us to come to any conclusion about them. (4) A French observer (Jouin) tried thyroid treatment in 5 cases of fibromyoma of the uterus, and noted marked diminution in the size of the tumors in 2 cases, and diminished hemorrhage in 3.

The fact that in myxedematous children and cretins the thyroid treatment is associated with notable growth in height has led some observers to try its effects in dwarfed children not myxedematous, to see if their development could not be helped. I have collected 10 such cases, 3 in idiotic children, and 6 in whom the lack of development was mainly physical. A considerable increase in height was observed in all the cases, but the mental symptoms were not improved.

This brings me to speak of insanity as treated with thyroid. About 60 cases are on record—25 improved. Out of all who have tried the treatment, Bruce, an English writer, is apparently the only one who feels sanguine as to its use. Twenty-one out of the 25 improved cases are his. He considers it "a valuable addition to the alienist's armamentarium in certain cases," and advises its use in cases of melancholia whose spontaneous

improvement had come to a standstill; in maniacal cases without signs of dementia and in stuperous cases in early stages. He finds that women do better under it than men, an observation parallel to the results in obesity. It is contraindicated in emaciated patients, and those who eat poorly, and in cardiac disease. Bruce's experience related to 30 cases, 21 of which showed improvement, amounting to recovery in 14. Clarke, a Canadian writer, finds like Bruce, good results in cases of stupor—several benefited, one or two recovered, one relapsed.

At the Danvers Asylum and the McLean Hospital for the Insane, the thyroid treatment has been tried to a limited extent without any beneficial effect on the mental symptoms. At the Worcester Insane Asylum, Dr. Scribner used it in 10 chronic cases without any effect except a decided loss of weight, amounting in 4 cases to over fifteen pounds.

In epilepsy one author finds good effects and one bad effects from the treatment.

Although starting without any strong bias against the possible utility of thyroid in exophthalmic goiter, I have not been convinced by the literature that a further trial should be given it. Out of 85 cases published, 22 improved, 40 did not, and 23 were worse. The size of the goiter has diminished in many of these cases, but without corresponding general improvement. The number of those made worse is about equal to those benefited, and three-fourths show no improvement. Nevertheless, some actual cures are recorded in obstinate cases, and there seems a possibility that in a certain type of the disease it may do good. In no other disease, however, does it so often do positive harm. On the whole, there is very little reason for hoping that it will do good in this condition.

Tetany.

The last use of thyroid feeding, of which I shall speak, is in tetany. Of twelve recorded tetany cases subjected to it, only four showed improvement, but two of these were very obstinate and long standing cases, and have shown no relapse in a period of five months. Possibly, here, as in many other conditions, thyroid feeding may help to distinguish different types within each disease, according as they are or are not affected by the thyroid treatment. It

[1] Counted as two cases in total.

may be that there are the thyroidal and non-thyroidal types of obesity, psoriasis, tetany, insanity, etc. In the case of obesity, we seem to be already in possession of some criteria by which we can tell beforehand whether or not a given case is likely to be benefited. In the other conditions, such criteria are very scanty, but there seems to be some ground for hope that thyroid treatment may enable us to split up several supposed entities of disease, as we have split up jaundice and asthma, and show them to be simply symptomatic of a number of different underlying conditions.

To sum up the impression gained from the study of the literature of thyroid feeding, it seems to be: (1) Of great value in simple parenchymatous goiter, especially in young people. (2) Of considerable value to reduce weight in obesity, especially in the anemic, flabby types, and provided the relapse is prevented by diet and exercise. (3) It seems to deserve a further trial in obstinate cases of psoriasis, sclerodema, and lupus; also in tetany, certain phases of insanity, and retarded development in children. (4) In exophthalmic goiter it rarely does good and often harm. (5) In chlorosis, rickets, diabetes, and tuberculosis, the evidence is not sufficient to warrant inference.

A few words as to the form in which the thyroid is to be given. Many of the most successful recent results in Germany have been with the fresh gland, raw or fried. There is but little doubt that this is superior to the German dried extracts. Whether or not it is superior to English and American extracts, we have no sufficient evidence to show. The fresh gland is very unpalatable, but may be given by the rectum.

Attempts have been made in Germany to extract the active principle of the thyroid gland, and Fraenkel's "Thyreoantitoxin," and Baumann's "Thyrojodin," are now being experimented with in Germany. The latter preparation is an iodin compound, and considerable success in the use of it was reported by Ewald and others at the Wiesbaden Congress. The dosage is exact, and it is free from some of the unpleasant toxic qualities of the dried preparations of the gland.

I have alluded to some dangers attending the use of thyroid preparations. The resultant bad symptoms are probably of two kinds: (1) the physiological action of an overdose of the gland itself, and (2) ptomain poisoning due to products of decomposition included in the dried preparations of the gland. Their two chains of symptoms are often lumped together under the name of "Thyroidism."

"Thyroidism" is first shown by rapid pulse and palpitation; cardiac oppression and angina, even fatal in a few cases, may occur. Anorexia, nausea and vomiting, diarrhea, lassitude, malaise, faintness, vertigo, headache, and pain in back and extremities, are not uncommon; hysterical manifestations and, rarely, aphasia, monoplegia, convulsions, and even coma occur. With some preparations urticaria, erythema, and eczema are produced. An odor to the skin and perspiration is sometimes noted. I have had two patients speak of this.

'In those predisposed to diabetes by inheritance a temporary glycosuria may occur,' and V. Noorden hopes that we may in the future be enabled to make an early diagnosis of diabetes.

In giving thyroid preparations, the best guide is the pulse. *Any considerable quickening or palpitation should lead us to discontinue the drug until the cardiac action is again normal.* There are no dangers in the use of the drug, provided we begin with small doses, from one to two grains of American extracts, and gradually increase, watching the pulse. It should never be given to a patient who cannot be closely watched.

SUPRARENAL EXTRACT IN ADDISON'S DISEASE.

Since Rollesboue's remarkable Goulstonian lectures on the suprarenal bodies, in which he recommends a trial of the extract of these glands for Addison's disease, a certain number of cases have been reported. I have been able to collect only twenty cases, out of which nine have been considerably improved. The use of the preparation is still in its infancy, and these cases represent trials of watery, alcoholic, and glycerin extracts, as well as of the gland itself, raw or dried, so that it is misleading to lump them all together and judge of the results. The various fluid extracts are evidently very inferior to the gland itself, dry or raw. One case, under the care of Dr. F. C. Shattuck, at the Massachusetts General Hospital, I had an opportunty to observe. Dr. Shattuck felt no doubt of the diagnosis, and no improvement occurred until after the use of the dried extract of suprarenal body. The patient is now, to all appearances, well, and has been so for four months. An absolute diagnosis of Addison's disease is, I believe, impossible without an autopsy, so that a certain amount of doubt is thrown on the apparent benefit derived from this mode of treatment in genuine

[1] V. Jaksch (Fourteenth Congress, Wiesbaden) doubts whether the reduction of copper in these cases is always due to sugar.

SUPRARENAL EXTRACT IN ADDISON'S DISEASE.

TABLE VI.

Author.	No. of Cases.	Result.	Remarks.
Parkinson	1	Worse.	Died soon after.
Turney	1	Worse.	Died soon after.
Ringer and Phear	1	Temporarily better.	Died soon after.
Pitres	2	Worse.	Subcutaneous use.
Spellman	3	2 no effect. 1 greatly better but relapsed.	Using alcoholic extract.

Addison's disease; but when we have such benefit recorded in cases diagnosed by such clinicians as Pye-Smith, Osler, and F. C. Shattuck, we cannot help feeling hopeful about the treatment, especially as on physiological grounds, there seems to be reason to expect that it would work well.

Experiments with suprarenal extract have shown it to have the property of increasing blood-pressure by stimulation of the vagus and cardiac muscle, and also of contracting the caliber of the periphery arteries. Acting on this suggestion, Bates has employed it as a local astringent and hemostatic in operations on the eye, and also in glaucoma and conjunctivitis. Oliver and Clark have employed it with benefit in a case of diabetes insipidus, and its use has also been praised in three cases of diabetes mellitus, and in hysteria, and neurasthenia, with loss of vasomotor tone, and in certain forms of anemia.

It is evidently a powerful medicinal agent, and severe toxic symptoms have been recorded in connection with its use, but on the whole, there seems to be some reason to feel hopeful about its result. Certainly, it deserves a farther trial in a disease for which no other treatment has hitherto availed anything.

EXTRACT OF PITUITARY BODY IN ACROMEGALIA.

The records of this subject are very scanty. I have been able to collect only nine cases of its use. Five of these appear to be more or less improved. Three of these are reported by Marinesco, an Italian. The headache and other pains improved, the general condition was better, and the extremities smaller. One case was able to move the hands better and walk with less fatigue than before. One favorable case comes from England, under Bramwell's care, and another from Germany. In these two, thyroid extract has previously been tried without success. In the German case reported by Mendel, the knee-jerk, which had been absent, returned, and the condition of the teeth and gums improved.

Thyroid treatment has also been tried for acromegalia in ten cases, six of which have improved, and four have not. As both the thyroid glands and pituitary body are sometimes found diseased at autopsy in acromegalia, it may be that the simultaneous use of both extracts will be found useful.

BONE-MARROW.

Since ordinary forms of anemia yield readily to treatment by other drugs, it is chiefly in pernicious anemia and leucemia that we have hoped for help from bone-marrow. But I have been unable to find accounts of a single case of undoubted pernicious anemia which has shown any permanent improvement. In the case of Danforth, which attracted so much attention at the time it was reported in October, 1894, there has since been relapse and death, and there is no reason to suppose that the temporary improvement had any connection with the treatment. The cases of Frazer and Bigger both lack a satisfactory blood examination, and their subsequent progress after the first few months is not recorded. The other cases reported as improved (nine in number) are defective, either as to diagnosis or as to the subsequent progress of the case. Temporary improve-

ments are so common in pernicious anemia with any treatment, as well as without any, that no case can be called cured unless the improvement has persisted at least two years (Cabot). There are no records of improvement in leucemia and and four not improved.

In secondary anemia and chlorosis we have a considerable number of favorable reports. Fifteen cases of chlorosis and chlor-anemia, are all said to have improved, and in two of these, Blaud's pills are said to have had no effect.

Seventeen cases of secondary anemia, including four of rickets, are also recorded as improved. But these anemias are easy to cure, as a rule, and as marrow contains iron, it is not remarkable that improvement was noticed.

Two cases of anemia infantum, pseudo-leucemia, are reported by Combe, a French observer, as cured by bone-marrow, but there is reason to doubt the diagnosis.

On the whole, there seems to me to be less reason to expect good results from the use of bone-marrow than from any of the other animal extracts I have mentioned.

CONCLUSIONS.

1. Thyroid extract is certainly valuable.
2. Suprarenal extract we have reason to hope will be proved so.
3. Pituitary extract we cannot judge of as yet.
4. Bone-marrow is in all probability useless.

THE IMPORTANCE OF EARLY DIAGNOSIS AND TREATMENT OF INFLAMMATION OF THE MIDDLE EAR.[1]

BY J. HENRY FRUITNIGHT, M.D.,
OF NEW YORK;
VISITING PHYSICIAN ST. JOHN'S GUILD FREE HOSPITAL FOR CHILDREN, NEW YORK CITY; FELLOW AMERICAN PEDIATRIC SOCIETY AND NEW YORK ACADEMY OF MEDICINE, ETC., ETC.

IT has been said that "an otitis externa any one could cure, but an otitis media no one could cure." How lamentably true this may be after an otitis has become chronic! But it need not be so if vigorous treatment is energetically carried out at the inception of the disease. Lack of recognition of the importance of instituting early treatment of an otitis, is in no small degree responsible for this pessimistic aphorism. How often has it been observed that when the nurse or mother calls the attention of the physician to an otorrhea, the latter would shrug his shoulders and with a reassuring smile nonchalantly say, "Oh, that does not signify, it will take care of itself, just wash out the ear with a little warm water and borax and it will soon be all right."

Again, that ancient fetish, dentition, will be pressed into service and made to play the rôle of scapegoat to palliate the unpardonable carelessness of the attending physician, who explains that the otitis is a relief to the child while teething, with which it is dangerous to interfere.

I most earnestly deprecate and protest against such a *laissez faire* policy, because such lax methods of treatment tend to confirm the opprobrium formulated in the opening sentence of this paper. The large number of people with total or even partial impairment of hearing impresses upon us the importance of early treatment in these cases.

It is a matter of observation that the deficiency in hearing is not the only baneful result of a neglected otitis, but that this loss of the sense of audition is accompanied, in the majority of instances, with an arrest of mental development, or at least a curtailment of mental capacity. The emotional side of the patient's nature also suffers a change, making him morose and suspicious, bringing out the ignoble traits of character, often making the victim a misanthrope, and sometimes a degenerate with criminal tendencies, in consequence of being, through his affliction, denied the advantages of the beneficent social influences and left to his solitary brooding. Though very much has been accomplished in late years in the amelioration of the condition of these unfortunate ones, the facts just stated will be admitted by all.

This demonstrates how important it is to begin treatment early in this class of cases, while from a politico-economic standpoint it is no less important to diminish the number, or, at least, to prevent additions to the number of degenerates and dependents who may become a public charge.

I was present recently at a necropsy held on a child in whom an *otitis media purulenta chronica* had existed for some time. My observations then prompted me to prepare this article. Brain symptoms had developed indicating abscess in that organ, and the skull had been trephined. The autopsy revealed an extension of the disease to the meninges and cerebral sinus, with suppurative thrombotic foci scattered through these parts. I have met with a number of such cases of extension of the inflammation and of the suppurative process to the cerebrum, all resulting fatally.

The frequency of otitis as a complication or sequel to so many of the prevalent diseases should make us conscious of the importance of early care, but, as in so many other things, this very frequency

[1] Read at the meeting of the Northwestern Medical and Surgical Society of New York City, April 22, 1896.

has bred the contempt of familiarity, and the otitis is apt to go untreated.

During the recent epidemic of measles in this city, from October, 1895, to the present writing, many hundred cases of the disease have been treated by me. Of this large number about seventy-five per cent. developed an otitis.

Treatment was inaugurated with the very first appearance of ear symptoms, and I am happy to say that no case was left uncured.

I have also observed, during the past winter, that an otitis complicated, or rather followed, many cases of simple inflammatory diphtheria.

La grippe has been very prevalent among children in my practice during the same period, and a very large number of those attacked have also suffered from otitic disorders. I recall a number of families among whom two or three children presented ear symptoms. In these cases of diphtheria and influenza treatment was also commenced as soon as symptoms of ear trouble were observed. Sometimes in cases of pneumonia in children, when the case is apparently doing well, and improving, there is a sudden change for the worse, a rapid increase in the fever, accompanied by much restlessness and often delirium; examination of the chest does not reveal any exacerbation of the disease, but in all probability an otitis has started up, explaining the violence of the symptoms. In pneumonia of the apex in children this is apt to occur. If such a complication is recognized, early treatment is of great importance. Meningitis, both cerebral, and, more particularly, cerebrospinal, is in very many cases accompanied by an otitis, and these cases are the ones in which treatment, even if begun early, is least efficient.

By the early treatment of an otitis complicating the diseases just enumerated I have saved many from total or partial deafness, which demonstrates that this early treatment is most essential to secure that result before much destruction of tissue shall have taken place. In fact, I hold that the case is not treated in its entirety unless close attention is given to the complicating otitis.

What has been said suggests that it may be *apropos* to treat of the therapeutic measures employed in these cases of otitis. Before considering the treatment to be directly applied to the affection of the ear it will be wise and necessary to pay attention to the state of the mucous membranes of the nasal and nasopharyngeal cavities. It is now conceded by old observers that a great number of cases of otitic disease have their *fons et origo* in a diseased condition of those parts. The inflammatory and catarrhal condition which may exist in the nasal and nasopharyngeal tract will naturally demand treatment in order to benefit the difficulty in the auditory canal.

With this general statement, without particularizing the method or kind of treatment to be employed in the affections of the upper air-tract, I shall dismiss its consideration, as it does not fall strictly within the lines of this paper. Of the treatment of the otitis I shall speak a little more fully. At the outset of the attack, if much pain be present, I order an instillation in the ear of from three to four drops of a watery solution of muriate of cocain of five to ten per cent. strength, as frequently as may be required to allay the pain. The solution should be warmed by placing the bottle containing it in warm water before it is dropped in the canal. In this connection I would enter my protest against the use of oily liquids in the ear, for, in my opinion, they are surgically unclean, offering a nidus for the culture of germs and the accumulation of filth. Nor do I approve of stuffing cotton in the ears, except when there is exposure to a direct current of air, and then it must not be pushed into the canal, but fitted in to conform with the contour of the auricle, in short, laid with the rim of the auricle *covering* the aperture of the auditory canal and not entering its lumen. Warm effusions and vapors I also employ to allay pain. Relays of small bags filled with poppy-heads or camomile flowers heated have also been used with satisfaction. Sometimes irrigation with warm alkaline watery solutions will give relief. If the case be quite severe counter-irritation, particularly in the form of sinapisms to the tragus and mastoid process, is of value. If the inflammation be of a higher grade, leeches may be employed to the mastoid process and tragus, care being taken that the leech does not make its way into the ear, which can be avoided by plugging the latter while the creature is engaged in abstracting the blood.

If the drum membrane be very tense and highly congested then a paracentesis is indicated for the relief of the symptoms.

If an otorrhea, serous or purulent, shall have followed, it has been treated as follows: If it be serous, then a simple warm astringent solution containing sulphate of zinc, or boracic acid, or the like, is employed to irrigate the canal. If the discharge be purulent, from eight to ten drops of the peroxid of hydrogen are dropped into the ear, which is to be flushed out with as much warm water as may be necessary until the outflow returns clear. These irrigations are re-

peated as often as the discharge reaccumulates. A fountain syringe is recommended, but the nurse is warned not to place it at too high an elevation lest the force of the current be too strong, and thus become harmful. After irrigation the canal is gently wiped dry with absorbent cotton until no vestige of moisture remains. Thereupon two or three drops of an alcoholic solution of boracic acid of the strength of from five to ten grains to the half-ounce, are instilled in the ear, warmed in the manner already spoken of. These drops are used whether the discharge be serous or purulent in character. The patient may complain that these boracic-acid drops smart; if not too severe that is of no consequence, in fact, I hold that it is a good indication, for it means that it is stimulating the healing process. Occasionally blood will flow from the ear when the alcoholic boracic-acid solution is used. In this event the stimulation is too active. Under such circumstances, or when the smarting is very painful, a reduction in the strength of the solution is indicated.

If the discharge from the ear is very persistent and resists this treatment, I order irrigation of the canal with a solution of nitrate of silver of from five to ten grains to the ounce, of which solution from one dram to half an ounce is to be added to a pint of warm water. I have frequently seen one irrigation control an otorrhea which had persisted for weeks, and it will be seldom necessary to continue the use of the nitrate of silver solution long.

These cases of otorrhea are sometimes apt to be long drawn out and well calculated to try the patience of both physician and nurse. The physician should encourage the nurse or mother to persevere in the treatment, assuring her that in the end success will follow her efforts, and that if she discontinued the treatment the disease would certainly not get well, but would, in all probability, eventuate in partial or total deafness.

I shall speak of the practice of insufflation of powders, sometimes employed in the treatment of this affection, only to condemn it. In my experience the powder readily commingles with the discharges, forming a hard caked mass, which in its turn becomes a source of irritation and acts prejudicially, both mechanically and chemically interfering with the surgical cleanliness of the parts, often increasing the pain and giving much trouble afterward in its disintegration.

If the patient exhibit any constitutional taint, as strumous, syphilitic, tubercular, or rachitic, the treatment approved of in such cases must be brought into play to reinforce the topical therapeusis.

THE CAUSATION AND THERAPEUTICS OF NERVOUS DISEASES.[1]

BY CURRAN POPE, M.D.,
OF LOUISVILLE, KY.;
PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM AND ELECTRO-THERAPEUTICS IN THE LOUISVILLE MEDICAL COLLEGE; CONSULTING NEUROLOGIST TO THE LOUISVILLE CITY HOSPITAL.

THE medical mind has been recently directed toward the presence and excess of uric acid in the excretions of persons suffering from various forms of nervous troubles, and some French investigators go so far as to state that nervous disease and uric-acid diathesis are one and the same thing. This is based largely upon the investigations and statements of Haig and Bouchard. I believe, however, that the position assumed by Herter and Horbaczewski is correct, and that uric acid, largely derived from nuclein, is the detritus of tissue-waste and a resultant of nerve-functioning, and that the presence of uric acid is an indication and a manifestation of nutritive and digestive disturbance.

We find many cases of nervous trouble, especially those of a functional nature, associated with large quantities of uric acid in the excreta. Many interesting facts, such as the injection of the blood of an animal which has been very much fatigued into one that is rested, the resting animal showing signs of fatigue, demonstrate the effects of these effete products. Many waste products of an intricate nature are produced and thrown off into the circulating medium during the expenditure of force by the organism, and these must be carried off through the channels of elimination to prevent the danger of auto-intoxication. We must get rid of the waste products of nutrition if we would utilize the beneficial and assimilative properties of the hemic pabulum. A person's system containing effete material resembles a city whose vast system of streets has remained uncleaned for some time, with ashes and garbage in the roadway and orange and banana peels on the sidewalk. The physician should be the street-cleaning department, the board of health, with its disinfectants, and the head of a police inspection system that will prevent a reaccumulation. When this interesting condition is presented for our consideration, what can be deduced from it for therapeutic purposes? Elimination must precede nutritional treatment, and the careful and proper regulation of food, or, for a while, its restriction in very narrow limits, together with the drinking of large quantities of water—hot, cold, plain, distilled, alkaline, or mildly laxative, as the

[1] Read before the Kentucky State Medical Society.

case may require, will greatly assist toward recovery.

Hodge found, after excessive functionating of a nerve-cell, a diminution in the size of the cell, a lessened power to absorb staining reagents (showing imperfect assimilation and nutrition), and later vacuolation, as the substance of the cell is used. The nucleus then becomes jagged and irregular in outline. After a while it is impossible for the cell to send out impulses, and it requires a period of rest for recuperation and a storing of energy. Vas and Mann, quoted by Starr, also found that when activity reaches the point of fatigue, a shriveling-up occurs, changes go on in the chromatin, which is used up so that the fatigued cell does not absorb the staining reagents. A neurasthenic is frequently weakened by hereditary entailment, his nerve-centers poorly constructed, or his vascular supply just sufficient to maintain him during health at a moderate pressure while at work. When he begins to increase this pressure, we find that the cell begins to suffer from imperfect nutrition. With this come defective elimination and irritation, resulting in the production of various forms of headache, vertigo, inability to work and concentrate the mind, great irritability, and general malaise. In this age, every energy is directed toward an increase of wealth; and with the night, instead of rest and recuperation, the struggle to obtain social position goes on apace. I often wonder what the next generation will be, and how they will stand the strain to which their fathers and mothers have succumbed. There are a large number of men and women who are living absolutely on the brink of nervous bankruptcy, who have no reserve nerve-force in case of some sudden and exhaustive demand upon the system. That most beautiful mechanism, which in health regulates the caliber of the blood-vessels—the vasomotor system—becomes unstable, and the sufferers become victims of manifestations which are, in health the result of natural emotional causes. Pain (and worry, anxiety, and tribulation are simply modifications of pain) is accompanied by vasomotor change; and those of you who have had to do with the neurasthenic, know that the hot flash, the sudden flush, the fulness of the head, the excessive sweating, and variations in the renal secretions are merely manifestations of this vasomotor instability.

And this, again, is not a condition favorable to the elimination of those effete materials that are in themselves toxic and irritating to the nervous system.

How can a happy result be best brought about? We have to consider (1) elimination, (2) unstable and defective nerve-force, (3) nutritional disturbances, (4) irregular or unstable vasomotor supply. It requires a combination of methods that, alas! the pharmacopœia does not offer; and while medicinal agents are required, nay, are of benefit, still I do not believe that they are capable alone of curing any case of this character. Massage is of advantage in certain well-selected cases, but I believe its range is limited and its results to be obtained only by the most careful regulation of its force and duration. As a rule, too much is given, both in quantity and in force. Electrotherapeutics offers a better field, and in galvanic, faradic, and static currents we find that, by selecting cases, excellent results may be obtained. In my opinion, hydrotherapy is by far the most satisfactory, pliable, and useful remedy that the medical profession possesses.

Rest is frequently prescribed for these cases, and just as frequently as it is, it fails. The reason for this is apparent. The exhausted nerve-cells have not sufficient inherent recuperative power to utilize what pabulum is brought to them. It is this non-attention to the eliminative process that robs rest of many of its advantages. I have found rest beneficial at the end of a course of treatment, when the vitiated nerve-elements have been restored to their normal condition, and the patient is in a position, as it were, to "clinch" the advantages gained by treatment. In these cases sleep is of signal benefit, particularly that which is obtained through the hypnotic influence of hydrotherapy. Medicinally, nervin and hematic tonics are indicated, and strychnia, quinia, iron, arsenic, and zinc head the list. If much digestive trouble exists, stomach-washing, the mineral acids, and gentle laxatives are indicated.

As time goes by, the belief grows in force, and is strengthened by experimental and clinical knowledge, that underlying epilepsy is an autoinfection, arising from the stomach and intestinal tract, coupled with imperfect or defective elimination. Careful regulation of the diet and strengthening of the vasomotor system is the one way by which at least one-third of the cases of this terrible disease may be combated.

I have a case just now in which this treatment is beautifully exemplified. Formerly under heavy doses of bromid the attacks were recurring, and the patient was reaching a condition of despair. Under a carefully regulated diet and two weeks of careful observance of her case, I was able to prevent the recurrence of the attacks, which were somewhat periodical, by keeping the intestinal

tract well cleaned out and disinfected, and utilizing such hydrotherapeutic methods as insured active and well-distributed blood-supply. In the Flechig treatment in those chronic, depraved, and most trying of cases, we have a system of treatment which, I believe, is the best that can be offered to these patients. I have found that during the primary stage, or the one during which opium is used, that much of its evil effects, soporific, depressing, and infective (from constipation), can be overcome by using eliminative measures, in the shape of large quantities of water internally, and the douches in their various modifications, externally. In the second stage, or that during which bromid is used, a cup of black coffee in the morning (only), the use of a hot-air bath for five minutes, followed by a rain bath and a good rubbing, will entirely remove the languid and depressed feeling and prevent the acne from appearing.

Where a headache has lasted for a long time, we should certainly examine the renal secretion, as in certain cases I have found unquestioned evidence of incipient or actual Bright's disease. Many headaches are lithemic in origin. Diet and elimination form the keynote to the treatment. I have seen cases of headache lasting from twenty to twenty-two years, and due unquestionably to meningeal thickening, relieved by the systematic application of static electricity and hydrotherapy. I have one patient, who, eighteen years ago, had an attack of meningitis of the convexity, and who has ever since suffered from intense headaches.

There is no question in my mind that this case, for instance, had in and around the meningeal thickening considerable vasomotor disturbance, which, under overwork and emotional strain, was evidenced by the increased throbbing, fulness in the head, feeling of tension, and increased pain. He improved from the first, under hydrotherapy.

A tolerant nerve-cell is a nerve-cell that is well fed, just as a tolerant, amiable, "happy-go-lucky sort of a fellow" is one that is well fed and moderately obese. This is a very important factor in the prognosis of some cases that are usually pronounced incurable, from the simple fact that while the meningitis is not cured, taking my case as an example, still we can frequently establish toleration and obtain what, to the patient, is a true cure. To us it may be symptomatic, but to him it is a verity.

The importance of acute infectious diseases as the origin of many nervous troubles, functional and organic, cannot be overestimated. For this reason they deserve careful consideration, especially diphtheria, grippe, scarlatina, and those diseases that are accompanied by the pyogenic microorganisms. My records show large numbers who directly trace their neural breakdown to that scourge, the grippe, while the paretics and ataxics will nearly always be found to have some vascular derangement, to which we can reasonably lay the cause of the disease. Weigert holds that the process which we term sclerosis in the nervous system is merely a manufacture by nature of a supporting substance within the brain or cord, to take the place of an atrophied nerve-cell or fiber. His order of causal factors is (1) overwork, (2) exhaustion, (3) atrophy of the neurons, continued for a time and then followed by a growth of connective tissue in the form of sclerosis, limited to a functional tract. It seems to be a conservative process on the part of nature to increase the supporting network as the cellular substance shrinks, and if this be true, and it is the most rational of all explanations of these scleroses, then the statement that these diseases in their primary stages are curable holds good. The writer made this statement in an article published about two years ago, and while that statement was based purely on clinical experience, he now has the statement of one of the greatest living pathologists to fortify him in the position he assumed.

CLINICAL MEMORANDUM.

A CASE OF POISONING BY SCOPOLAMIN.

BY MATTHIAS LANCKTON FOSTER, M.D.,
OF NEW YORK;
ASSISTANT SURGEON MANHATTAN EYE AND EAR HOSPITAL.

A FEW years ago scopolamin in the form of the hydrobromid and hydrochlorid was introduced into ophthalmic practice as a mydriatic. Its action is very energetic and of brief duration, and for a while it did not seem improbable that it might supersede other mydriatics, particularly for the purpose of determining errors of refraction. Observations recorded by a number of competent investigators show that after the instillation into the conjunctival sac of from one to five drops of a one-fifth of one per cent. solution of either of these salts of scopolamin a maximum dilatation of the pupil is obtained in from ten to sixty minutes, while paralysis of the ciliary muscle proceeds *pari passu* with the pupillary enlargement, and the eye is then ready for examination. This effect gradually passes away, and has totally disappeared at the end of five or eight days.

If the action of scopolamin upon the general system could be eliminated no better mydriatic for refraction work could be desired, but unfortunately it not infrequently produces toxic symptoms of various degrees of severity. No fatal result has, I think, yet been reported.

According to the observations made by Dr. Smith, an effect upon the heart usually becomes manifest in from

five to ten minutes after the instillation of a single drop of a one-fifth of a one per cent. solution, the pulse becoming soft and compressible, while the rate is usually lessened, sometimes to a marked degree, but is occasionally increased in rapidity or becomes irregular.

A number of cases of poisoning have been reported, in which dryness of the throat, muscular weakness, dizziness, nausea, restlessness or sleepiness, a weak and rapid pulse, and sometimes a flushed face, have been the prominent symptoms, but in none of these did the symptoms as reported appear as grave as in a case which occurred in my evening clinic at the Manhattan Eye and Ear Hospital while under the care of Dr. Kendall in August, 1895. It is for this reason that I feel impelled to place the following case on record:

A young laboring man, who had been treated for a considerable time for a mild form of trachoma, was found to be astigmatic, and it was decided to be advisable to examine him under the influence of a mydriatic. Scopolamin was chosen, and four instillations of one drop of a one-fifth of a one per cent. solution were made in each eye at intervals of ten minutes, commencing at 8 P.M. Fifteen minutes after the last instillation, a little over an hour after the first, the patient complained of dizziness, and was obliged to lie down. This was followed by dryness of the throat, nausea and attempts to vomit, flushing of the face, decrease in the strength and increase in the rapidity of the pulse, symptoms which increased with alarming rapidity for half an hour, and reached their culmination in about two hours. At the end of half an hour the pulse was over 160 per minute and very weak, the face was growing darker until it became mildly cyanotic, the patient was unconscious and wildly delirious. The muscles of the extremities were frequently and strongly convulsed. When at the worst it took the strength of several men to hold him, and some doubt was expressed by the gentlemen gathered about him whether his struggles were the result of the active delirium which was present or to spasmodic contractions of the muscles from the irritation of the drug. The pharyngeal muscles appeared to be in a state of paresis.

These symptoms began to abate in about two hours under energetic treatment with morphin and whisky, and the improvement progressed so rapidly that the patient was able to leave the hospital and walk home at 6 A.M., ten hours after the first drop was instilled. Nausea and dizziness persisted for a day longer. The recovery from the mydriasis was in the usual time.

It should not be inferred from such a history as this that scopolamin is too dangerous a drug to use, but it should be understood that it is too dangerous a drug to use without proper care and precaution. Certain individuals are without doubt more susceptible to its influence than others and the rapidity of its action suggests a way in which it may be possible to avoid giving an overdose. The observations in regard to its effect on the ciliary muscle show that the time necessary for complete paralysis varies from ten to sixty minutes, and that the quantity of solution of the usual strength required to produce this effect is from one to five drops, hence it is wise to test the accommodation before the second and all succeeding instillations to avoid the unnecessary use of the drug after the ciliary paralysis is complete. Another practical precautionary measure is to occlude the tear-ducts by means of pressure by the patient's finger as soon as a drop has been instilled into the conjunctival sac. This prevents the passage of the solution through the lacrimal passages into the nose and its absorption through the mucous membrane. When these two precautions are observed the danger of poisoning is reduced to a minimum.

MEDICAL PROGRESS.

A New Method of Entero-anastomosis.— SOULIGOUX (*Gazette heb. de Méd. et Chir.*, July 23, 1896) has devised a new method of intestinal anastomosis, which consists in suturing two loops of gut without opening them. With a strong clamp he pinches, in a longitudinal direction, the free border of the two intestinal loops, and then stitches them together along one margin of the compressed areas. These areas are then touched with caustic potash, and the suture completed around them. The cauterized portions of the gut necrose, and fall into the lumen of the intestine, and communication is established. In animals, this takes about forty-eight hours. The operation has been performed upon man several times with success.

Chaput has performed a similar operation, using a Paquelin cautery in place of caustic potash. If the stomach enters into the anastomosis, he first removes the muscular coat of the portion involved. Retention of feces is a contraindication. The chief advantage of the operation is the rapidity with which it may be performed.

The Treatment of Ileus.—As a result of his investigations, NAUNYN (*Sep.-abdr. d. Mitteil. aus d. Greuzgebiet. d. Med. u. Chir.*, 1 Bd., 1896) gives relatively exact rules for the treatment of ileus, as follows:

1. The prognosis of the operative treatment of ileus is most favorable on the first and second day of its existence; on the third day it is markedly worse.

2. The best results (seventy-two per cent. of recoveries) are obtained in those cases in which obstruction is due to a rupture, not including cases of strangulated hernia.

3. In primary peritonitis, this condition and not the resulting ileus, must determine the operation.

4. (*a*) In chronic intestinal stenosis, the necessity for an immediate operation does not often arise. (*b*) The seat of obstruction can usually be made out exactly if it is located in the duodenum, descending colon, sigmoid flexure, or rectum; otherwise it can only be guessed at. (*c*) Strangulation can often be diagnosed, and demands an immediate operation.

5. In three classes of ileus an exact diagnosis is possible. (*a*) Ileus from foreign bodies, *e.g.*, gall-stones; (*b*) valvulus of the sigmoid flexure; (*c*) intussusception.

Of treatment other than surgical, Naunyn says:

(1) Avoid cathartics. (2) Far better is the employment of large enemata of water, or injections of oil, five to sixteen ounces. Injections of air are less serviceable. (3)

Opiates should not be given in large doses. (4) Washing out the stomach is advisable whenever there is fecal vomiting, or the stomach is overfull. (5) Food and drink should be reduced to the minimum. (6) Puncture of distended intestinal coils is of doubtful value.

Etiology of Serous Pleuritic Effusion.—In the *Zeitschrift f. klinische Medicin*, Bd. 29, H. 5 and 6, the cause and nature of serous effusions in the pleural cavity are thoroughly discussed. The author of the article, ASCHOFF, placed before himself three questions:

1. Is every idiopathic pleurisy, *i.e.*, a serous pleuritis without known cause, tubercular in its nature?

2. Is there such a thing as an acute isolated rheumatic pleurisy, which is to be looked upon as equivalent to a preceding acute attack of rheumatic arthritis?

3. Do serous pleuritic effusions ever contain pyogenic organisms without later becoming purulent?

Bacteriological examinations were made of two hundred serous exudates, with the following results:

Serous effusions are nearly always free from pus-producing microörganisms. If the latter are present, the exudate will become purulent, except possibly in exudates containing pneumococci. Purulent pleuritic effusions sometimes heal completelv without operation.

The occurrence of isolated rheumatic pleuritis is questionable—at least it must be very rare. The pleuritic effusions occurring in rheumatism are almost invariably the result of a cardiac lesion. No special benefit has been observed by the administration of salicylic acid.

The so-called idiopathic effusions are almost always tubercular. They may, however, disappear perfectly.

Cholecysto-gastrostomy.—TERRIER (*Gazette Hebdom. de Méd et de Chir.*, July 16, 1896) reports a case in which, upon opening the abdomen for obstruction in the gall-duct, due to cancer of the pancreas, he performed the unusual operation of forming an anastomosis between the gall-bladder and the stomach, which was more readily accessible than the intestine. Recovery followed the operation, and there was no disturbance due to the outpouring of bile in the stomach. The patient died some months later of disseminated carcinoma, and upon autopsy, the anastomotic opening was found to be ample. Only two other cholecysto-gastrostomies have been performed.

Elimination of Microorganisms by Glands.—BIEDL and KRAUS (*Centralbl. f. Inner. Med.*, July 18, 1896). By a series of experiments upon dogs, the authors found that bacteria injected into the veins are eliminated by the kidneys and liver, but not by the submaxillary salivary gland. In one instance the bile which, before the injection, was sterile in thirteen minutes, contained the injected staphylococci. The saliva remained sterile.

The experiments, besides establishing the fact that normal blood-vessels may be traversed by microörganisms, also show the character of the liver as an eliminator of germs from the blood.

Results of Five Hundred Vaginal Hysterectomies.—JACOBS (*Centralbl f. Gynäkol.*, No. 29, 1896) finds that the mortality of five hundred hysterectomies for various causes is only 3.4 per cent. Among the cases are forty-nine of carcinoma uteri without a single death. Two of the deaths were from intestinal obstruction, brought about by adhesions of the intestine so low down in the vaginal region that the author thinks they might have been avoided by vaginal tamponade. Practical directions for the operation are given: Short clamps hold better than long ones. For the first part a thermocautery is preferable to the knife as saving time and blood.

When the extirpation is complete, Jacobs ties off the clamps on the broad ligament, stitches the peritoneum together, and thereby renders the patient more comfortable, and avoids danger of intestinal adhesions and herniæ in the vagina. In inflammatory cases, drainage of the peritoneal cavity is necessary, gauze being employed.

Valvular Rupture Following Traumatism.—DREYFUS (*Gazette hebdom. de Méd. et de Chir.*, June 7, 1896) has found that blows upon the chest, or falls, or sudden violent efforts, may produce rupture of any of the cardiac valves, more often of the aortic or mitral ones. The accident is marked by the signs of an acute insufficiency, and the diagnosis lies between rupture of the aortic or cardiac valves, angina pectoris, and pseudo-angina pectoris.

The prognosis is grave, depending upon the extent of the rupture and the condition of the mycocardium. Possible complications are secondary infections, infective endocarditis, rupture of the septum, aneurism, and embolism. The medico-legal point is brought out that a blow on the chest may kill a person without external evidence of the violence, and that an examination of the cardiac chambers may be necessary to show the cause of death to be rupture of some of the valves.

THERAPEUTIC NOTES.

The Successful Treatment of Hay-fever.—DR. SETH SCOTT BISHOP (*The Laryngoscope*, 1896, No. 1, p. 21) considers that the uric-acid hypothesis explains the symptoms. In addition to local treatment, meats, sweets, wines, and beer, should be reduced as much as is possible, and the diet limited to fruits, vegetables, milk, and fats. The treatment of the lithemia is substantially based upon Haig's work, and consists of salicylate, salicin, and lithium. Tablets, each containing morphin $\frac{1}{12}$, atropin $\frac{1}{600}$, and caffein $\frac{1}{6}$ grain, are efficacious in checking the sneezing, watery discharge, and stenosis.

Painless Extraction of Teeth.—SCHLEICH'S (*Therap. Monatsch.*, May, 1896, p. 269) cocain solution, employed to produce infiltration anesthesia before extraction of a tooth, is as follows:

℞	Hydrochlorate of cocain . .	0.2 grm.
	Hydrochlorate of morphin . .	0.025 "
	Sterilized chlorid of sodium . .	0.2 "
	Antipyrin	2. "
	Guaiacol	2 drops
	Sterile distilled water, q. s., or .	100 grm.

Anesthesia, produced by injecting this fluid, is said to continue about half an hour.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, SEPTEMBER 12, 1896.

THE PRISON LABOR QUESTION.

ABOUT a year ago the NEWS[1] discussed several aspects of the section of the New York State constitution which prohibited the employment of prisoners at productive labor. The evils of such legislation were pointed out, not only from an economic, but also from an ethical point of view. Among other things, it was shown that the burden of increased taxation, resulting from the necessity to make good the deficit consequent upon the withdrawal of such labor, would eventually fall upon the community, and with especial weight upon those least able to bear it, and whose own wages would not be increased by reason of the new legislation. This position is amply sustained by the annual report of the Brooklyn Penitentiary, recently issued, from which it appears that during the year ending July 31st, the net earnings and receipts of the penitentiary fell off from $32,754.33 to $7,981.36, although the reform had been in operation for but a few months. As the running expenses of the Brooklyn Penitentiary are upward of $140,000 per annum, it will be seen that a large sum of money that has hitherto been derived from the salutary occupation of the prisoners, will have to be raised by increased taxation. What is true of the Brooklyn Penitentiary in this connection is equally true of other penal institutions in the State of New York. We have dealt here only with the economic aspects of the question, as its other aspects have already been considered at considerable length.

RECENT PROGRESS IN MEDICINE.

SERUMTHERAPY AND LUMBAR PUNCTURE.

FOR one who reads European medical literature to any extent, it is not possible to resist the conviction that the serum mode of therapy is rapidly establishing itself as an enduring principle of wide application in therapeutics. During the past six months, all other forms of serumtherapy have been so overshadowed by the antitoxin treatment of diphtheria, that knowledge of them is much less universal than it otherwise would be.

The treatment of diseases produced by streptococci has been developed to a considerable extent on the European Continent, and particularly in France, where its introduction was due largely to the labors of Marmorek, Charrin, and Roger. In a case of hemorrhagic septicemia reported by Ballance and Abbott, in a recent number of the *British Medical Journal*, the infection was so severe that lymphangitis, adenitis, vomiting, chills, high temperature, scarlet, septic erythema, puffy face and eyes, and mental stupidity, were noticed within the first thirty-six hours after the infection. At the end of the second day, the patient's condition became alarming; the temperature was nearly 105°, pulse 150; rash, brilliant red and hemorrhagic, mental hebetude, vomiting, bleeding from the nose and pharynx, and slight albuminuria were present. Sixty hours after infection the first injection was given. Within six hours improvement set in, followed by rapid recovery.

The injections were made into the loin and abdominal wall, and after the first eight (of 3.5 c.cm. every four hours) had been given, the succeeding twenty were increased each to contain 7 c.cm. The writers suggest the possible use of the serum in fracture of the skull in which there is risk of suppurative meningitis, in acute necrosis, acute septicemia and pyemia, rapidly spreading gangrene

and cellulitis, erysipelas, general suppurative peritonitis, and in the septic complications of middle-ear disease. They believe that the proper way of administering it is to begin with moderately large doses, 20 c.cm., to give the injections frequently, and as soon as beneficial effects are manifest, to reduce the dose to about 7 c.cm.

The serum used was from the blood of asses. The ass receives during several months increasing injections of living virulent streptococci. The antistreptococcic serum has therefore antimycotic rather than antitoxic powers. Tests applied to the serum after each injection showed a progressive increase of bactericidal properties. The fact that streptococci may remain in the blood of animals for several days after their infection, makes it imperative to remove all chance microbes by filtration through porcelain.

It is well known that the danger of death in scarlet fever is enhanced greatly by the suppurative complications that follow that disease. Baginsky of Berlin, has put Marmorek's serum to the test in fifty-seven children affected with scarlatina. He says that it is so antipathic to the complications of this disease that it reduces the mortality from thirty to forty per cent.

Josias (*Semaine Médicale*, May 20, 1896) has had a larger experience with the antistreptococcic serum in scarlet fever. He injected forty-nine children in the first period of the disease, each with 5 c.cm. of serum obtained from sheep. With the exception of slight urticaria, no bad symptoms resulted. He also injected ninety-six children with horse serum in the second stage, with an average quantity of 10 c.cm., but some of the patients received as high as 90 c.cm. Complications resulted in twenty-nine of these cases. The mortality in cases which used the sheep serum was only about one-half as great as in those in which no serum was used.

It must be remarked that the difference in mortality rates, which these writers speak of, may be accidental, for not infrequently much greater variations in the death-rate of epidemics of scarlet fever occur, even if the cases are allowed to take their course without particular treatment. If the serum treatment can be given without danger of any ulterior consequence, and if there are grounds for belief that it may prevent the suppurative complications and sequelæ of this disease, it deserves the fullest trial. Apparently, the only word of warning necessary is that great care be used in the preparation of the serum.

The diagnostic value of lumbar puncture, or of puncture of the subarachnoid space in the lumbar region, is now universally conceded. Weichselbaum has described a special microörganism which occurs in pairs and quadruplets, lying with their broad sides opposed, not lanceolate, and situated chiefly within the cells. On account of its location the name of *Meningococcus intracellularis* was given to this organism. Weichselbaum claimed that it was the cause of meningitis. This claim was contested, but it is now known that the pneumococcus, which for a time was considered the causative element in meningitis, produces a purulent form of that disease, while the intracellular coccus of Weichselbaum is the cause of epidemic cerebrospinal meningitis. It is between these two forms of meningitis, particularly, that lumbar puncture may be utilized to make the diagnosis. If the fluid withdrawn contains the cocci of the one form or of the other, and if cultures made from it produce the respective diseases in susceptible animals, the diagnosis of the variety of meningitis will be made, and the prognosis confirmed, for in epidemic cerebrospinal meningitis, the prognosis is immeasurably better than in the purulent form.

Heubner (*Deut. med. Woch.*, July 2, 1896) was able, by means of an examination of fluid from the subarachnoid space, to establish just this distinction. The operation of tapping the subarachnoid space in the lumbar region is such a simple and inconsiderable one, that it is well perhaps to remember that in some conditions, such as tumor or abscess of the cerebellum, it is not unattended by real danger, not to speak of the aggravation of the symptoms which it causes.

JOSEPH COLLINS, M.D.

ECHOES AND NEWS.

Argon and Water.—Argon has been combined with water by Professor Villard, of the Paris École Normale, at a pressure of 200 atmospheres.

A New Disinfectant.—A gas, obtained by the partial combustion of methylated spirits, has been successfully

tried as a disinfectant by the Antwerp Medical Commission. It is non-toxic, and free from corrosive action, and is said to destroy all trace of bacteria.

The Recrudescence of St. Ronan's Well.—On September 10th, the pumproom at St. Ronan's will be opened. The access of ordinary spring-water had destroyed the prestige of this spa, familiar to all readers of Scott. There are two waters, a saline and a sulphur.

Longevity of Human Life Increasing.—A German statistician has calculated that of every 1000 persons, 100 reach the age of 75, 38 the age of 85, and only 2 reach 95. In the seventeenth century, the average duration of life was only 13 years, in the eighteenth, 20, in this century 36.

Milk Inspection in New York.—Milk Inspector Dockery of New York City, has just made his annual report, which shows that in nine months he has inspected no less than 3700 cows, and condemned 7300 gallons of milk. He is the first man in his office to enforce the regulations, and the result has been a marked decrease in infant mortality.

The Plague in Hong Kong.—The total number of cases of bubonic plague in Hong Kong from January 1st to July 20th, was 1158, of whom 1013 have died. Dr. Yersin, a French bacteriologist, claims to have discovered a serum which cures the disease and confers immunity against it.

Philadelphia Hospital.—A position as permanent resident physician at the Philadelphia Hospital is vacant, and is shortly to be filled. For the proper incumbent, the position is a most desirable one, offering large opportunities for a wide experience. A fair salary is paid, and board and residence in the Hospital are provided.

Carrier Pigeons in Medical Practice.—A doctor in the Highlands of Scotland, whose patients are scattered over a wide district, takes carrier pigeons with him on his rounds, and sends his prescriptions by them to the apothecary. He leaves pigeons, too, with distant families, to be let loose when his services are needed.

Formaldehyde in Consumption.—Dr. Francisque Crôtte has been using gaseous inhalations of formaldehyde, assisted by the application of electricity to the chest, for aborting consumption. Out of about eight hundred cases, he claims to have successfully treated six hundred. A committee of the French Academy of Sciences has been appointed to examine and report upon the treatment.

Mississippi Valley Medical Association.—The program of the meeting of this Society in St. Paul, September 15th to 18th, promises a feast of good things, both scientific and social. The expedition to Yellowstone Park is a feature of unusual attractiveness, and offers an opportunity which will doubtless be improved by all who can afford the time.

The Consumption of Alcohol.—Frenchmen consume more alcohol than other Europeans, according to figures put before the Basel Congress for Alcoholism. In the computation the amount of alcohol in light wines and beer is included. The average annual consumption of alcohol per head of population is 13 quarts in France, 10 in Switerland, Belgium, and Italy, 9 in Germany and England, 4 in Sweden, 3 in Norway, and 2 in Canada.

Tannoform.—In *La Belgique Médicale* Drs. G. de Buch and L. de Moor describe the therapeutic effects of tannoform, which is precipitated from a solution of tannin in formaldehyde by adding hydrochloric acid. The authors have used it externally in the treatment of old indolent ulcers, and internally in infantile diarrhea. It is said to combine the astringent effects of tannin with the antiseptic and drying properties of formaldehyde.

Obituary.—Dr. Alexander Buchannan, a specialist in pulmonary diseases, died at his home in New York, of tuberculosis, contracted, it is believed, from his patients. He was born in Glasgow, and began his medical studies in New York, but graduated from the College of Physicians and Surgeons of Glasgow. He returned to the United States, and has since practised in New York. He was the author of a number of treatises on consumption and other pulmonary diseases.

Condemned Tenements Destroyed.—The work of the New York Board of Health in tearing down condemned tenements continues. They have now attacked the rookeries in Chinatown. In several cases the owners of the houses had informed Chinese tenants that the Health Board had no legal right to destroy the premises, so the coolies remained till axmen began their attack on rotten timbers, when they swarmed out like rats. This movement will be sure to arouse owners to the necessity of putting their houses in proper sanitary condition.

New York Almshouse Abuse.—The Commissioners of Public Charities for a week past have been investigating the condition of the people confined in the almshouse. Enough has been learned to justify the assertion by President Croft that fully twenty per cent. of the inmates on Blackwell's Island are improper charges upon the city. This means that between four and five hundred people possessing means themselves, or having friends able to support them, are living at the city's expense. One inmate died a few days ago leaving $4000 in a savings bank.

Haffkine's Anti-cholera Serum.—Dr. Simpson, the health officer of Calcutta, who has been investigating the Haffkine cholera treatment for the past three years, has just issued his report. Among 654 uninoculated persons there were 71 deaths (about 11 per cent.), while among 402 inoculated persons in the same households there were 12 deaths, less than 3 per cent. Among 5000 coolies, working in the tea gardens in Cachar, 2000 have been inoculated. Fifteen of these were attacked by cholera and four died, but among the other 3000, 154 were attacked and 60 died.

Pasteur's Tomb.—The crypt under the principal entrance of the Rue Dutol Institute, which is to contain Pasteur's tomb, is rapidly approaching completion, and his remains will probably be transferred to it from Notre Dame on December 27th, the anniversary of his birth.

At the entrance of the vault is the following inscription in French: "Happy is he who carries within himself a God, an ideal of Beauty, and obeys it; an ideal of Science, an ideal of the virtues of the Gospel." In the carving of the interior are depicted the animals and vines that Pasteur rescued from disease.

Brooklyn's Water Supply.—For many years Brooklyn enjoyed a water supply of exceptional purity. The experience of the last year or two proves that this is no longer the case. As a matter of fact, Brooklyn has nearly exhausted the sources from which good water can be obtained on Long Island. Already it has been practically forbidden to draw any more from Suffolk County, and there are complaints in various neighborhoods that the local supply of water has been interfered with by the large draughts of the city. The question arises, where shall she go for a sufficient supply of pure water?

Montenegrins' Powerful Voices.—The Montenegrins are gifted with probably the most powerful voices in the world. The distance across which they can shout is extraordinary, and they are in the habit of carrying on ordinary conversations across a tract of country which the utmost shouting of an ordinary man could scarcely traverse. A few years ago, when a murder was committed near the Austrian frontier, the news was carried throughout the entire country, and the army was mobilized within a couple of hours, simply by shouting the news from cliff to cliff and from town to town, with the result that the murderers were quickly caught.

The Antagonism Between Chloroform and Hydrocyanic Acid.—Professor Hobday, in an article in the *Journal of Comparative Pathology and Therapeutics*, recounts a number of experiments made to determine the antagonism of hydrocyanic acid and chloroform. In the lower animals, chloroform kills by narcotizing the respiratory center, of which hydrocyanic acid is a very rapid excitant. In the first series of cases, in which respiration had ceased through the action of chloroform, Scheele's acid was injected subcutaneously, and artificial respiration resorted to. Professor Hobday is convinced that the use of the acid is a most important adjuvant in resuscitation. In the second series, the antidotal power of chloroform in prussic acid poisoning was shown.

The Cocain Habit in New Orleans.—A druggist of New Orleans, gives, in the *Picayune*, the following account of the use of cocain by the native darkies: "How on earth these ignorant people ever learned of the effects of this powerful and dangerous drug I am at a loss to say, but I know it as a fact that some drug stores in this city sell enormous quantities of the stuff to the darkies in five-cent packages. The demand for it is so great that they keep the stuff in little papers which they retail at five cents, and it is quite frequently the case that the darky doesn't even open his mouth to say what he wants, the trade is so well established. He simply goes into the drug store, throws down his nickel on the counter, and is given a cocain package without his ever opening his mouth—just as he would slouch into a beer-joint and get a glass of beer." Such an abuse should receive the prompt attention of the Board of Health.

What is an Accident?—A physician of Essex county, New York, while driving between Hayne and Ticonderoga, was overcome by exhaustion arising from an injury sustained a year previous. He stopped his horse and proceeded to give himself a hypodermic of morphin. His horse started suddenly and the needle was driven further than he intended. Cellulitis ensued and he was disabled for twenty-two weeks. He brought suit against the Interstate Casualty Company, which had insured him "against bodily injuries sustained through external, violent, and accidental means." The presiding judge of the Circuit Court of Essex County dismissed the complaint. The Albany Court of Appeals, by a majority of three to two, decided that the jury should have been allowed to determine whether the injury was accidental or not. The court held that the injury could not be called accidental, if it was caused by the morphin or by the uncleanliness of the needle.

The Nomenclature of Diseases.— The second decennial revision of the "Nomenclature of Diseases," embodying the most recent views on the nomenclature and classification of diseases, and prepared by a committee of the Royal College of Physicians of London, has been issued. Tetanus, actinomycosis, foot and mouth disease, pellagra, Hodgkin's disease, and diabetes insipidus appear in the list of the so-called general diseases for the first time. Tetanus is placed between septicemia and tuberculosis among diseases due to specific microörganisms. Rheumatic fever, despite the evidence in favor of its being a specific febrile disease, appears between pellagra and rheumatism and gout. Membranous croup is made synonymous with diphtheria. Puerperal fever has been expunged from the official nomenclature, and pyemia, septicemia, or sapremia in puerperal women, are to be described as puerperal pyemia, septicemia, and sapremia respectively. In the appendix, containing a list of vegetable parasites, the tubercle and anthrax bacillus are given as the cause of these diseases, but the diphtheria bacillus is described as occurring in the lesions of diphtheria, and the spirillum of Asiatic cholera as occurring in the intestinal epithelium and contents in cholera.

Greater New York Charter.—The sub-committee of the Greater New York Commission has prepared chapter 19 of the proposed charter, which provides for a Department of Health, under a Health Commissioner to be appointed by and removed at the will of the Mayor, with a term coextensive with that of the Mayor. The chapter provides that the department be divided into two bureaus; one under a "sanitary superintendent," who must be a physician, and the other under a "register of records," who, without fees, must record births, marriages, deaths, and inquests. The Health Commissioner has power to declare and abate all public nuisances. The proposed law practically embodies existing provisions relating to the registry and duties of plumbers, superintendence of improvements in and erection of buildings, the prevention of nuisances

from uncleanliness, defective drainage, and the disposition of garbage and other waste. Vaccination is provided for, and authority is given to the department to close streets, forbid communication, and quarantine neighborhoods, as well as vessels and buildings. In tenements erected after June 16, 1897, all sleeping-rooms must have a window, at least twelve square feet in size, admitting light and air directly from the street or yard.

Enforcement of the Mercantile Establishments Law.—This law, which regulates the employment of women and children in mercantile establishments in New York, went into effect September 1st of this year. Already the Board of Health has divided the city into inspection districts, and inspectors have begun the work of seeing that the law is enforced. The law contains the following provisions: "No male under sixteen years of age and no female under twenty-one years of age shall work more than sixty hours in any one week. No child under fourteen years of age shall be employed. A register shall be kept of the names, etc., of all employees under sixteen years of age, and no child under the age of sixteen years shall be employed without first obtaining a certificate from the Board of Health. Suitable and proper washrooms and water-closets are to be provided, and water-closets assigned to women and girls to be wholly separate and apart from those assigned to males. Suitable seats for female employees must be furnished. Basements where women and children are employed can be so occupied only after a permit for the same has been granted by the Board of Health. Forty-five minutes shall be allowed for the noonday meal in each establishment."

SPECIAL ARTICLE.

DISCUSSION OF THE TREATMENT OF HEMOPTYSIS.[1]

THE subject was introduced by Charles E. Quimby, M.D., of New York, who spoke of the diversity of method used by various practitioners and teachers, and the great need of setting our approval on what is useful and, at the same time, condemning injurious measures.

Dr. Quimby said: Of the two causative factors, vascular tension and degenerative changes in the vessel walls, it is evident that the latter are not subject to modification within such time as will render them a basis for treatment of an existing hemorrhage. The possibilities of influencing the arrest of hemoptysis must, therefore, be sought in one or more of three universally accepted lines:

1. Modification of vascular tension.
2. Increase in the coagulability of the blood.
3. Mechanical and chemical aids to clot-formation.

In the first of these there has been the greatest apparent antagonism of methods. So long as we recognize a gangrene, due to the prolonged use of ergot, no one can well deny that extreme arterial constriction produces capillary anemia. But, all the vasoconstrictors produce systemic even more strongly than pulmonic contraction, and the consequent increase of arterial tension must be transmitted back through the heart and pulmonary veins until it is felt in the capillary circulation of the lung. Even if this were not important, there would seem to be the greatest uncertainty of producing and maintaining the requisite degree of constriction to cause persistent capillary anemia, and anything short of that must increase the hemorrhage, for even involuntary muscles soon become exhausted and refuse to respond to the sharpest stimulation. Most serious of all appears to me the objection derived from the pathology of the disease. It is not questioned that mural degeneration of the bleeding vessels is the most important cause of the hemorrhage, yet it is in these vessels and those immediately adjacent, which also cannot be supposed to have escaped entirely degenerative changes, that muscular contraction is absolutely necessary. If but one of them is unable to respond to the stimulus of ergot, or to bear the increased strain, all arterial contraction becomes not only useless, but absolutely harmful. This argument, with certain clinical evidences that ergot quite as frequently augmented as retarded bronchial hemorrhage, led me, some eight years since, to abandon the vasoconstrictors and their ally, the ice-bag, which I had been taught to use, and to direct my arterial therapeutics to the development of low tension in the pulmonary circulation. This is accomplished by both active and passive measures. Since muscular action and mental anxiety are cardiac and vascular stimulants, complete rest, both physical and mental, is imperative, not only for its direct influence in quieting the heart's action, but also to increase the influences of other measures. Personally, I make no examination of the chest until the hemorrhage has ceased, as none of my therapeutic measures are influenced by the location of the trouble, it being understood, of course, that sufficient is known to differentiate a hemorrhage of phthisical from one of cardiac or other origin. An initial dose of some preparation of opium I regard as routine treatment in all cases, for not only is the general nervous excitement, so often the predominant cause of the vascular disturbance, controlled thereby, but rest of the affected lung is also secured through the coincident arrest of cough. In cases of profuse hemorrhage, however, probably less is gained by complete arrest of cough than is lost in the dangers incident to the retention within the lung of large amounts of blood. Morphin should here be used to modify, not to arrest the cough.

Active diminution of pulmonic vascular tension is most fully obtained by, first, general lowering of blood-pressure; second, diversion of the blood from the lung to other parts. To secure the former, my main reliance is upon aconite, which is given in a full initial dose, and repeated as required to maintain the desired vascular quietude. In cases which present the symptoms of shock from the outset, although often with rather a tense pulse, morphin alone, in small repeated doses, not only relieves the shock but lowers vascular tension and equalizes the circulation.

The blood may be diverted from the lung to the thoracic wall, the alimentary mucous membrane, and the abdominal glandular organs. To this end, in all except mild cases, I apply counter-irritation by means of turpen-

[1] Meeting of the American Climatological Association at Lakewood, N. J., May 13, 1896.

tine stupes or mild mustard plasters, to the entire back and sides of the thorax, endeavoring so to temper them as to maintain a sharp capillary hyperemia, which is continued until all bleeding has been absent for some hours. In mild cases, a similar and sufficient derivation is more easily obtained by way of the alimentary canal alone.

Having seen some of the "old women's remedies" of my youth reappear in the garb of "modern scientific discoveries," I was led to a consideration of the use of salt, which has resulted in my using it constantly for hemoptysis, upon what I consider a truly scientific basis. Undoubtedly, a more pronounced and persistent effect is gained from the Epsom or Rochelle salts given to the point of free catharsis, but I am convinced that a primary hyperemia of the alimentary mucous membrane is developed more speedily by reflex action through the gustatory nerves from salt taken in the mouth, and that this hyperemia is sufficient to have a decided and valuable influence on pulmonary circulation. I supplement its action by the more powerful salines in the more severe cases. Since the action of salt is purely reflex through the nerves of taste, its value does not depend upon the amount taken, but upon its persistent use. In very obstinate cases the more stimulating or irritant cathartics may be given.

As regards the remedies used to increase the coagulability of the blood or to produce a local astringent effect, the possibility of their reaching a bleeding point in any efficient amount, always seemed to me so remote that I have never yet prescribed one of the astringents.

Astringent inhalations seem, *a priori*, more reasonable than internal astringents, and a most gratifying experience in the mechanical treatment of pulmonary disease has led to some attempts in rather severe cases of hemoptysis to develop atmospheric compression of the bronchial vessels by compelling the patient to expire through a restricted opening, as a pipe-stem, straw, or even the compressed lips. A sufficient number of cases have not been seen to justify any positive statements, and the measure is presented rather as a suggestion.

In presenting a summary of my own treatment of bronchial hemorrhage, no claim is made of anything new; but simply that it is based upon a well-defined principle, has a definite object in view, and that the measures form a harmonious whole. It includes: 1st, rest; 2d, morphin; 3d, aconite or other vascular sedative; 4th, dry salt and a saline cathartic; 5th, counter-irritation; 6th, obstructed expiration. It excludes: 1st, astringents; 2d, ice; 3d, stimulants; and 4th, the vaso-constrictors.

The following statements are the answers in substance of the several gentlemen to this question: "Will you state just what you would do if called to a case of moderate or severe hemoptysis, it being assumed that it is a bronchial hemorrhage, dependent upon tubercular disease of the lung?" It was understood that the answers do not include what might be done as a placebo for the patient and friends, nor indicate treatment in detail.

Dr. Delafield affirms these two broad propositions: (1) Such hemorrhages are never fatal, and are dangerous to life only through the succeeding extension of the tubercular process. (2) No therapeutic measure has any appreciable effect in determining the arrest of the hemorrhage. He, therefore, limits his treatment to reassuring the patient and making him comfortable.

Dr. Draper follows a rather expectant plan of treatment in the milder cases, but when the hemorrhage is well defined in a case of definitely determined tuberculosis, his chief reliance is upon full and absolute rest in connection with opium, although he generally gives some ergot. When he has reason to believe that the hemorrhage is localized and forms a congested area about tuberculous deposit, he applies ice to the chest over the seat of hemorrhage. He never uses the mineral astringents.

Dr. Jacobi regards every bronchial hemorrhage in phthisis as presenting serious possibilities, having seen a primary hemorrhage prove fatal in a patient who had never presented any symptoms or been suspected of having any tubercular disease. He insists upon absolute rest, allows no talking, and makes only such examination of the chest as is necessary to determine the seat of the hemorrhage, which can be done by auscultation alone. He allows the patient but little fluid. In therapeutics, he relies mainly upon acetate of lead and opium, though he directs that digitalis be given at the outset, followed by injections of ergot from time to time. The lead he gives in divided doses, uniformly through the day, and thinks it has been condemned by others because used in too small doses. He states that an adult patient may take from two to four grams of acetate of lead in twenty-four hours, and continue the dose for from two to four days. The lead is given in combination with opium, amounting to daily doses of from one to four decigrams, the indications for the opium being the general quieting effect. The digitalis, on the other hand, he says, should be given in one or two large doses of from eight to ten minims of a good fluid-extract at the outset, and repeated in from six to eight hours. The ergot also is given in an initial full dose, and repeated as may be necessary to maintain arterial contraction. Externally, he applies ice over the seat of the hemorrhage, and ligates the lower extremities in severe cases to retard venous flow. In all cases the bowels are opened freely until the hemorrhage ceases.

Dr. Janeway insists upon absolute rest in all cases, not allowing any physical examination even, except auscultation, until at least four days after the hemorrhage has entirely ceased. Therapeutically, he employs opium, both for its influence on the general nervous excitement, and to quiet the cough when that is prominent. For a direct effect upon the hemorrhage itself, he regards atropin as preferable to ergot. He gives cathartics to obviate the constipating effects of the opium, and thus to avoid the dangers incident to straining at stool. When the pulse is frequent and strong and not quieted by the opium, he uses aconite. Externally, he applies the ice-bag or counter-irritation to the affected side, rather giving the preference, if any, to the counter-irritation. In case the hemorrhage is prolonged and not arrested by the above treatment, he resorts to inhalations of turpentine, with the proviso that they must be begun carefully, and at once stopped if they excite an irritative cough. He does not employ astringents, but if he did, acetate of lead would be the one chosen.

Dr. Kinnicutt gives absolutely nothing by the mouth. He ascribes the very greatest importance to rest, absolute and continuous, physical and mental. Recognizing not only the prominence of nervous excitement and mental shock, and their influence in producing vascular activity, but also the physical and local disturbance produced by cough, he employs morphin, hypodermically, to control the former and moderate the latter. He does not employ ice externally, except in the more severe cases. He has absolutely no faith in astringents or ergot.

Dr. Peabody similarly bases his treatment upon that complete rest, which is made possible and fully obtained by hypodermics of morphin. He lays rather more stress, however, upon the value of ice externally for its action in causing a reflex contraction of the pulmonary vessels, and constantly employs ligature of the extremities in all severe cases. Negatively, he condemns all astringents as absolutely bad, except acetate of lead, which is thought to have a slight value in cases of moderate and persistent oozing, but to be entirely worthless in severe hemorrhage. He also specifically opposes all inhalations.

Dr. A. A. Smith also regards absolute all-round rest as the *sine qua non* in the treatment of bronchial hemorrhage, and he pays special attention to relieving mental anxiety from fear, in addition to securing the usual physical quiet. His medication is begun by a hypodermic of morphin, which he specifically states is *not* to be combined with atropin, on account of the effect of the latter in stimulating the circulation. In addition, he uses bromid of sodium when there is great mental excitement. If the hemorrhage starts with a rise of temperature, he uses one of the coal-tar series, of which phenacetin is considered the best. They are intended to quiet an excited circulation, and their dosage is to be governed by this effect. He allows patients to continue the use of salt as a placebo, and is not displeased if it causes nausea, as that is attended by a diminished circulation. Dr. Smith makes special mention of continuing the opiate for several days. He also places his patients on a milk diet at once, and, after allowing them to get up slowly, still restricts their diet, forbidding for some time all red meats, stimulants, and stimulating food. He regards all the astringents as utterly worthless, and ergot and ice, externally, as equally bad.

Dr. A. H. Smith insists upon rest and opium as the basis of all treatment in pulmonary hemorrhage, making special mention of the dangers from percussion and an over-zealous physical examination. Morphin he uses for its quieting effect and to moderate cough. If the pulse is hard, tense, and small, or if the patient suffers from a sense of oppression in the chest, he uses nitro-glycerin. More commonly he gives ergot, which he regards as especially valuable when the pulse is soft and weak, and in cases of distinctly capillary hemorrhages, which are moderate but persistent. For the astringents he has no use.

Dr. William H. Thomson lays no great stress upon rest, unless the hemorrhage comes on with high temperature, or there is reason to believe that the bleeding was started by exercise or physical strain. He relies almost entirely upon acetanilid and atropin, which he gives about every three hours, in doses of from three to four grains of the former combined with $\frac{1}{100}$ of a grain of the latter. In cases which give the history or present the physical evidences of an antecedent pleurisy, he straps that side of the chest firmly, believing that the tension from old fibrosis is often a prominent cause of these hemorrhages. He would insist also upon such quiet as would prevent strain of pleuritic adhesions. He does not employ the astringents or ergot, and makes no mention of any external applications or inhalations.

The treatment of bronchial hemorrhage, as deduced from these reports by a majority vote of eight to one, would be upon the general plan of vascular sedation with a lowered blood-pressure, and would include the use of: (1) Rest; (2) morphin; (3) vascular sedatives; (4) ice, perhaps (?) to which may be added in the same line, as having been mentioned without opposition; (5) saline cathartics; (6) ligation of the limbs; and (7) counter-irritation in place of ice. It would exclude the use of astringents or vaso-constrictors.

John H. Musser, M.D., of Philadelphia, made a report on the treatment of hemoptysis as practised by thirteen physicians of note in that city. The following is an analysis of the methods adopted:

1. *Rest.*—This, as was naturally expected, was enjoined by all. In nearly every instance it was urged that the rest should be in the recumbent posture. A number, however, urged that the patient should be in a semi-upright position, or the shoulders elevated. The internal use of opiates was advised by most of the writers, of the bromids by one person. The cough is to be controlled, and this is obtained by the use of opiates also.

2. *Local applications.*—Cold on the chest, in the form of ice usually, was advised by five of the reporters. In two of the five, its use was advocated in hemorrhages in the second or third stage of tuberculosis only. Most of them required the ice to be applied over the affected part.

3. *Diet.*— This was referred to by two only. One advised liquid diet, the other a readily digested but not low diet.

4. *Inhalations.*—The use of inhalations was objected to by three of the reporters, and advocated by one, who suggested that it must not be used if there is much cough.

5. *Dry cups.*—One of the reporters suggested drying-cup if there appeared to be congestion of the lungs.

6. *Internal remedies.*—The internal remedies advised may be divided into three classes: (1) Drugs to quiet the nervous system and allay the cough. (2) Drugs to allay arterial excitement. (3) Astringents. All enjoined the use of opium with the exception of two, both of whom, I think, overlooked its use. Morphin, however, was objected to by one very strongly. Professor Hare believes that the use of morphin causes more blood to be sent into the leaking blood-vessel of the lung, and advises the bromid of sodium in full doses by the rectum if it cannot be given by the mouth, and, if the pulse is strong, combined with chloral in doses of five or ten grains. Arterial sedatives were advised by two of the reporters. One thought well of the use of aconite in the hemorrhage of the early stage of phthisis, or of antipyrin in one- or

two-grain doses with morphin. Another thought that cardiac sedatives were admissible when given in moderate doses for hemorrhage in either the first or second stage. By some, astringents were advised without qualification; by others, their use was admitted, although their value was doubted. Thus, one reporter says he uses ergot in early hemorrhages with grave doubt; another, that he uses ergot and gallic acid, but does not believe they are of much account. They are given, however, with the hope that they may be of service. The following are recommended: Ergot or ergotin by the mouth or hypodermically, turpentine, gallic acid, fluid extract of hydrastis, the oil of erigeron, acetate of lead, sulphuric acid, *Lycopus virginica*. Gallic acid is advocated by the majority of the reporters. Ergot is advocated by five. Its use is not mentioned by four, and two report against it absolutely, and two others consider it of doubtful use. Acetate of lead has two advocates, turpentine two, and the other astringents one each. One of the reporters considers turpentine the only hemostatic of any value; another thinks turpentine or terebene of greater service than any other drugs in the late hemorrhages of tuberculosis, particularly if combined with morphin and antipyrin. Common salt was advised by one of the reporters,

Most of the reporters agreed that the treatment was the same, whether hemorrhage took place in the first or later stages. One of them insisted on small doses of astringents in the first stage, and of large doses in the latter stages. Another insisted on the local use of ice in the latter stages only; another, that turpentine should be used at this period. One insisted that the recumbent posture should not be assumed when the hemorrhage took place late in phthisis, and that opium should not be given or the cough in any way allayed at this period of the disease, on account of the danger of the accumulation of blood in the air-cells. Apparently, from the above, no difference in the treatment of the two stages existed.

From this review it may be said that the treatment of hemoptysis, as followed out by representative practitioners in Philadelphia, includes rest, mental and physical, the local application of ice, the use of opium, and, with considerable doubt as to their value, the use of astringents of the class referred to in the above analysis.

Dr. Musser fully indorses the above in so far as rest, ice, and opiates are concerned; he is not willing to indorse the use of astringents. He would urge the use of dry cups in certain well-defined conditions, and favors the use of saline catharsis if the patient is robust, and the condition of the primæ viæ points to its necessity.

Algernon Coolidge, Jr., M.D., of Boston, reported the practice of eighteen physicians in Boston: Seventeen gave the preference to opium among drugs, ten preferring morphin as the best form of administering it. Three allowed codein as a substitute. Six used ergot as a routine measure, but of these, four doubted its usefulness. Eight found it useless, and two considered it positively harmful. Seven were opposed to high altitudes, while five considered high altitudes not contraindicated.

R. H. Babcock, M.D., reported the practice of twenty-seven physicians in Chicago. Of these, eighteen insist upon absolute physical rest in recumbent or semi-recumbent positions, and three added that they permitted no talking. Cold to the chest is ordered by thirteen, usually in the form of ice. Nine administer opium, and eight morphin hypodermatically. Ergot is employed by fifteen, a few, however, stating some doubt as to its utility. One said he thought ergot only proved efficient when in doses sufficient to produce nausea. One administers Tancret's ergotin, hypodermatically, in doses of from six to eight minims, and mentioned no other treatment. Eleven are positive that ergot has no efficacy. Six make use of acetate of lead, either with or without opium; two tannic acid, two gallic acid, one dilute, and another aromatic sulphuric acid. Six prescribed ipecac, five the syrup, and one the powder in an emetic dose, after the manner of Trousseau. Four gave aconite, and two *Veratrum viride*. Salt is recommended by seven, one of whom relies largely upon it. Four advise mild laxatives, but do not specify the particular laxative employed, except the advocate of salt, quoted above, who recommends phosphate of soda. One only employs sprays to the larynx and trachea of solutions of iron, liquor ferri subsulphatis, ten to twenty minims to the ounce, or the tincture of the chlorid of iron, from twenty to thirty minims to the ounce of water, repeated three or four times daily. One uses phenacetin internally, depending upon the cause of the hemorrhage, and after the attack, rest, light diet, and tincture of iron internally. Two speak of employing ligatures to the extremities close to the trunk during the attack, one specifying constrictions of the lower extremities to prevent the return-flow of blood to the lungs. With one, hemoptysis ceased twice after atropin, hypodermatically, had produced dryness of the mouth. The advisability of light unstimulating diet, was dwelt upon by three.

Dr. Babcock relies on the use of phosphate of codein, hypodermically, or by the mouth, to quiet the cough; syrup of ipecac to the degree of nausea; Hunjadi or Rubinat water to open the bowels. He employs a hypodermic injection of one-fiftieth or even one-twenty-fifth of a grain of atropia sulphate to stop hemorrhage.

Dr. S. E. Solly, of Colorado Springs, said: Hemorrhage from large vessels and large cavities is relatively more frequent in Colorado than elsewhere, though the general tendency of altitude, through lowering blood-pressure, is undoubtedly to diminish the frequency of hemorrhages, and this belief clinical statistics confirm.

The first great danger in profuse hemorrhage from a large vessel is the drowning out of the patient by the blood, and it is advisable to turn him in such a position that the blood can flow readily out of the mouth; the plan of laying him on his back in bed is the worst possible position when he is freely bleeding.

The application of ice to the heart seems to quiet the organ, and thus assist in checking the hemorrhage. I am skeptical about the value of astringents, such as tannic and gallic acids, nor have I been satisfied with the use of large doses of lead, as recommended by Williams.

My clinical experience has been favorable to the use of ergot in large doses, given subcutaneously, at intervals of from four to six hours in the twenty-four. I believe a

common cause of failure with ergot is its irregular and insufficient use and administration by the mouth. There are, however, cases in which ergot is absolutely useless.

I also regard atropin as an extremely valuable remedy in serious cases, particularly in those in which ergot has proved a failure. But it must be given, hypodermically, in large doses, such as the one-fiftieth of a grain. A small dose of atropin is not beneficial. Thus morphin is best given without the usual one-fiftieth of atropin. It is stated that atropin in small doses raises the blood-pressure, while in large doses it lowers it. The reason that atropin is often successful in cases in which ergot is a failure, may be because in certain conditions lowering the blood-pressure, as by large doses of atropin, is essential to success, though in certain other conditions, raising the pressure is no detriment, or not sufficient to offset the other beneficial qualities of ergot.

Opium in some form should always be given, as well as other suitable remedies, when it is desired to arrest the hemorrhage and check cough. But there are cases of congestion in which it is unwise to do this.

Dr. W. D. Robinson, of Philadelphia: I have used calcium chlorid with success, and find that given between the bleedings, it is of advantage.

Another agent that I use is morphin, given to the degree of profound narcosis. I have given one-eighth of a grain once in forty minutes, until the patient is deeply under its effect. By stopping cough and local irritation we put the parts in splints, as it were, until firm healing of the bleeding point obtains. The morphin in full doses, by which the patient is kept practically in unbroken, sound slumber for from eighteen to twenty-four hours, is especially efficient in cases of frequent recurrent bleeding. The drug that I have found most prompt and efficient in stopping a hemorrhage, has been the hydrochlorate of hydrastinin in one-fourth grain hourly doses, hypodermically.

Dr. Boardman Reed, of Atlantic City: Regarding the use of ergot in these cases, I have not found it of any value, and have even thought that in some cases the results were positively harmful by contracting the arterioles throughout the body generally, and thus raising the blood-pressure. The mineral astringents have done good service in my hands, especially the aromatic sulphuric acid and gallic acid. There can be no doubt that these drugs increase the coagulability of the blood and thus assist directly in lessening the tendency to hemorrhage.

Dr. R. C. Newton, of Montclair: I wish to say that bromid of potassium fills the indications in many of these cases, especially when used in conjunction with Dover's powders and an ice-bag to the chest. Each case must, of course, be managed according to the surroundings and the indications. Dr. Babcock's suggestion of large doses of atropin, hypodermically, is a very good one.

Dr. Jas. B. Walker, of Philadelphia: I am glad to hear Dr. Fisk speak of oil of erigeron. I have long depended upon its congener, oil of turpentine, in hemorrhages from mucous membranes, and am surprised at the few references to its use in text-book and journal articles. In hemoptysis, it is of special service, and this is not surprising when its hemostatic properties are so well known, and its appearance in the expired air a few minutes after its administration by the mouth, shows how quickly it reaches the scene of action. I usually administer it in five-minim capsules (sealed) every four to six hours. The use of the terebinthinates in hemorrhage was vaunted by John Hunter, he claiming that it was the only true styptic.

SOCIETY PROCEEDINGS.

THE NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, April 22, 1896.

The President, HENRY LING TAYLOR, M.D., was in the chair.

J. H. FRUITNIGHT, M.D., read a paper on

THE IMPORTANCE OF EARLY TREATMENT IN INFLAMMATION OF THE MIDDLE EAR.

(See page 289.)

DISCUSSION.

DR. E. S. PECK said that he had, during the past winter, seen more cases of the kind considered in the paper than ever before. A simple catarrhal otitis is easily handled; but when it becomes purulent, and is otitis of the tympanum attic, or roof of the middle ear, it is in a region which calls for special skill. He had seen the drumhead burst in thirty-six hours in a child who had a simple otitis, with very little pain and no temperature whatever. It is just here that a puncture of the drumhead is of great value. The puncture is easily made in the lower anterior quadrant of the drumhead, where it is least sensitive. The cavity of the middle ear, in a child, will contain perhaps not more than one or two drops, and in an adult not more than three or four. It is a simple matter to puncture the drumhead. The wound made by the knife will very readily heal. The tympanum attic is so thin that, in a young child, where the bone is not formed, it is easy to get basilar meningitis.

A life insurance company had recently asked him about the mortality from chronic otorrhea. From the best statistics he was able to get, there was one death in eight hundred cases of otorrhea over the age of twelve. When a chronic otorrhea has been purulent, and is accompanied with a green discharge, meaning the death of the bone, or a bloody discharge, the condition renders the patient a poor insurance risk; but if it is a manageable case of otorrhea, the man can be put on a better basis. In regard to the treatment, he used twenty or twenty-four grains of boracic acid to the ounce. He firmly believed in leeches, if they were properly used. The abstraction of two ounces of blood from the mastoid does a good deal for the relief of the congestion of the vessels of the middle ear. As to poultices, he preferred dry bran or calomel. He had used hot water several times a day for weeks in succession, but to control pain it is objectionable.

DR. S. BARUCH said he hoped Dr. Fruitnight would enlighten the members upon the early diagnosis of these cases. He had made it a practice in cases of measles

and scarlet fever to pull the baby's ears and to press around the mastoid process to ascertain if there was any tenderness there, and in that way had frequently discovered otitis, even before any symptoms were pronounced. He had not found powder so very objectionable in chronic cases.

DR. T. H. BURCHARD recalled a case of suppurative cellulitis just back of the external ear, in the space between the external ear and the mastoid process. A small abscess formed, and the pus had burrowed down into the tissue of the neck. As it did not yield to the ordinary methods of treatment, the consultant, thinking it was suppuration in the middle ear, proceeded to incise that, without giving the slightest relief. Dr. Noyes was called in, and an incision was made between the mastoid process and the external ear, evacuating half an ounce of pus, with absolute relief to the patient. He asked Dr. Peck whether a diagnosis of these cases in which the suppurative inflammation was outside the ear, but in the vicinity thereof, was not apt to be difficult.

DR. PECK replied that such cases were uncommon. It is not difficult to tell whether the trouble is internal or external. If it is external it goes away quickly—in from three to five days—if internal it is a matter of months.

DR. J. BLAKE WHITE considered powders harmful and dangerous. He had also known cases where middle-ear disease was caused by solutions forcibly drawn into the head for catarrhal affections within the nasal tract.

DR. S. H. DESSAU said he would not use powders to treat cases of acute otitis media, but had used them for the last fifteen years in the treatment of otorrhea, in children and adults. Dr. Burnett of Philadelphia had recently popularized the use of powders in the treatment of otorrhea, using boracic acid which has been saturated with a tincture of calendula or marigold. He uses it in the treatment of otitis media after the drum membrane has been incised or is ruptured.

DR. JOSEPH COLLINS said that students should be taught to remember that four conditions are especially likely to follow disease of the middle ear—leptomeningitis, sinus thrombosis, brain abscess, and disease of the mastoid as an entity. These conditions occur after measles, scarlet fever, and such troubles because of the anatomical conditions existing between the pharynx, the ear, and the Eustachian tube. The infrequency of death from otitis media purulenta is recognized, but an entirely different statement must be made as to the outcome of the sequelæ, such as brain abscess, and the other conditions mentioned. A sero-purulent discharge from the ear, particularly in children, is quite as dangerous as a decidedly purulent one. In children the portions of the temporal bone are not united. The facility with which pathological products can be transported into the surrounding tis sue is marvelous. If you have an ordinary serous discharge, with no microörganisms in it, the slightest change by which pathological microörganisms may go up into the middle ear, may make of that a dangerous condition. Therefore, no matter what the discharge is, or how slight, the necessity for treatment is urgent.

DR. WOODS HUTCHINSON (Professor of Comparative Pathology in the University of Buffalo) said that the disease is almost unknown in any of the graminivora, and almost unheard of among any of the domestic animals, other than the dog or pig. In the carnivora, particularly the dog, the mastoid is well developed, and mastoid disease and inflammation of the middle ear are quite frequent. The middle ear is a remnant of the gill-slit, the Eustachian tube and the outer ear forming the outer part. The disease has a tendency first to escape to the Eustachian tube, failing that, to prefer the dermoid and escape through the gill-slit, and that failing, it may force its way back into the respiratory passage and into the mastoid, and even there its pathway of least resistance is outward, toward the surface. The pus in the middle ear has to burrow its way in the direction of greatest resistance before it can make these dangerous attacks.

DR. BIESER said that a knowledge of the dangerous sequelæ which may follow emphasize the importance of the early recognition of inflammation of the middle ear. When the almost tissue-like thinness of the roof of the tympanum is considered, it is not surprising that occasionally abscess of the brain, or meningitis, or thrombosis of the venous sinus, or mastoid disease follows. He lately had a case in which a child had been suffering from chronic otorrhea. The physician told the mother that it came from the teeth and was all right, and would take care of itself. It did take care of itself. The discharge suddenly ceased, and when he saw the child it was a full-fledged case of meningitis. May not an explanation of external cellular otitis lie in the formation of a fissure which leads from the external auditory canal?

DR. SPENCE said that he did not believe that the general practitioner is alone to blame for some of these ills following middle otitis. Only two months ago he had a case of abscess of the brain, where the woman had had an otitis and consulted a specialist, who told her to keep her ear clean, and that was enough.

DR. BARUCH, JR., said that he had seen fifteen cases of acute mastoid disease operated on, and each one of them, of course, had been preceded by a long, chronic otitis media. Five of them died from abscess of the brain, having come in too late to be operated upon.

DR. FRUITNIGHT said that the cases reported still more emphasized the importance of early treatment. Most of his cases had been patients under sixteen years of age. As to diagnosis, it has been his practice in cases of infectious diseases, or even of catarrhal or mucous symptoms, to discover any trouble by pressing the mastoid process, and under the left lobe of the ear, to see whether the child winces; and also by ocular inspection, to see whether there is any swelling in the canal. He thought that the physician should insist upon treatment whether he has been called in for that particular thing or not.

PRESENTATION OF SPECIMENS.

DR. WHITE exhibited a specimen and reported a case of appendicitis in a boy seventeen years old, who complained of severe headache, weakness, and lassitude. On the 7th of April he came to the speaker with a high fever, and complained of considerable pain in the right iliac region. On the 11th his temperature was 105½° and pulse

120. He complained of nausea and vomiting. He had several chills, and all the symptoms pointed to appendicitis. The operation showed a catarrhal appendicitis, with no suppuration at all.

DR. GROWER presented a specimen and reported the case of a young man twenty-four years of age, who came into the office of Dr. Millbank, saying that he had heart trouble. On examination, there was found to be a distinct dilatation, enlarged heart, and an impulse at the fifth or sixth intercostal space on the right side. A hypodermic of strychnin was given, and the patient went home; about two hours after he died. Upon autopsy, an aneurism about the size of a large walnut, which had ruptured into the right pleural cavity, was found. There was an enlarged heart. The interesting point is the existence of a condition of this sort in a young man twenty-four years of age, with no history of syphilis. Most of these aneurisms that occur at so early a period are due to syphilis. Fraenkel has reported nineteen cases, in which nine had a distinct history of syphilis.

DR. GROWER also presented a specimen showing tuberculous ulcerations in the intestine of a child twelve years of age.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, June 10, 1896.

WM. M. WELCH, M.D., and the second vice-president, THOS. J. MAYS, M.D., were in the chair.

B. MEADE BOLTON, M. D., read a paper entitled

THE EXAMINATION OF CULTURES FROM CASES OF SUSPECTED DIPHTHERIA.

He stated that from May 30, 1895, until January 1, 1896, there were examined by the Bacteriological Division of the Philadelphia Board of Health, 1421 primary cultures and 1942 secondary cultures, a total of 3363 examinations. Of the first, 1207 were made from the throats of persons presenting clinical evidence of diphtheria, and 214 from the throats of healthy persons, who had been exposed to infection. The diagnosis of diphtheria was made by the attending physician in 557 cases; in the remainder the physician either stated that the case was not diphtheria, or left the diagnosis in doubt. In the 557 cases diagnosticated as diphtheria, bacteriologic examination showed the presence of diphtheria bacilli in 507, or 90.2 per cent. In 148 cases the physician stated that the disease was not diphtheria. The Klebs-Loeffler bacillus was found in 40 of these, or 27.1 per cent. Cultures taken from the throats of 214 persons exposed to diphtheria, but presenting no clinical symptoms of that disease, showed the presence of Klebs-Loeffler bacilli in 89, or 41.5 per cent.; 95, or 44.3 per cent., did not show the bacillus; and in the remainder the result of the examination was unsatisfactory. In 50 of these cases it was possible to determine that the bacillus persisted, on the average, for 13.3 days. In 460 cases presenting clinical symptoms, the length of time that the bacilli were present, dating from the appearance of the first symptom to the disappearance of the bacilli, varied from 7 to 96 days, the average being 28.3 days.

DR. A. A. ESHNER said that it must be a matter for gratification that there should be so close an accord between the clinical and the bacteriologic diagnosis. The diagnosis of diphtheria is attended with certain obvious difficulties, inasmuch as there are a number of affections characterized by involvment of the nose and throat—tonsils, pharynx, larynx—presenting clinical manifestations closely simulating those of diphtheria locally, but differing in virulence and lacking the profound constitutional intoxication. It is likely that many of these affections are infectious, that is transmissible, but differ from diphtheria etiologically. They may be designated diphtheroid, as resembling diphtheria but not dependent on the Klebs-Loeffler bacillus. It is to be borne in mind that the absence of the bacillus is not necessarily evidence that the disease is not diphtheria; the microörganisms may have been present and have disappeared, perhaps appearing in some secondary lesion. Besides, failure to find the organisms is not conclusive evidence of its absence. On the other hand, the bacillus may be present and the symptoms be so mild as to obscure the recognition of the disease. It is exceedingly important to appreciate the length of time —sometimes weeks—that the diphtheria bacillus may remain in the throat or nose and still retain its virulence. So-called pseudo-diphtheria bacilli are probably diphtheria bacilli that have lost some of their pathogenic activity.

DR. BOLTON added that investigation had shown that in the various anginæ but two microörganisms of etiologic significance are always found—the diphtheria bacillus and the streptococcus. According to this view the statistics cited show that ninety per cent. of cases presenting clinical symptoms of diphtheria are due to the diphtheria bacillus, and ten per cent. to the streptococcus. It has been pretty well proven that so-called pseudo-diphtheria bacilli are really attenuated diphtheria bacilli.

EDWARD JACKSON, M.D., read a paper entitled

THE PROFESSION, THE OPTICIANS, AND THE PUBLIC.

He pointed out that the use of correcting glasses is still extending, even where it is now most common; and their more accurate adjustment to the needs of the wearer is likely to enlarge their use still farther. The employment of the eyes for the seeing of minute objects at short distances becomes more general and more constant; and the need for glasses will continue and extend until there occurs some important change in the direction of our social development. Who shall measure the eye for glasses? is then a question of some importance. No doubt it will ultimately be done by those who can do it best and do it cheapest, and only long experience will demonstrate who these will be. In Dr. Jackson's opinion it will be done by a class of practitioners familiar with the general principles of medicine and surgery, and experts as to the diseases of the eye, and specially trained in the methods of measuring refraction and conditions of ocular muscular balance. In addition to the special skill required in the correction of optical defects, another reason why this work should be done by a special class of professional men is, that it requires time, thoroughness and exactness. The benefit derived from a pair of glasses is not proportionate to their approach to accuracy of correction; for often no

benefit whatever will be experienced until the approach to accuracy is really very close. Thus it is that the best service in this matter is the only kind of tolerable service; and if it is rendered by the refracting optician rather than by a medical man, the former must make an adequate charge for his time, or else retire from the business. The proper relation of the optician to the prescriber of glasses, and to the public, is closely similar to that of the apothecary, and both sets of relations are liable to certain abuses, such as bribes in the form of percentages for patronage. The remedy consists in that portion of the medical profession doing the special work giving better and cheaper service, and putting itself in communication with those who need such service. One reason why people patronize opticians is to be found in the fact that some doctors do not give the necessary time and attention to the subject of refraction.

DR. WM. THOMSON said that his experience justified what had been said in regard to the need of accuracy and care, and also, that no man could do excellent refraction work unless he had the temperament and a certain kind of fitness for it. The ophthalmologist cannot consider himself a mere specialist, but must keep well equipped in all that pertains to general medicine.

DR. L. J. LAUTENBACH contended that the remuneration of the oculist should be measured by the amount of time required in the management of the individual case.

DR. T. B. SCHNEIDEMAN pointed out that the correction of refractive errors implies also an inquiry into the condition of the fundus, the optic nerve, the retina, the choroid, the media, etc.

E. LAPLACE, M.D., read a paper on

THE SURGICAL TREATMENT OF INSANITY.

He pointed out that while surgical intervention must not be resorted to in every case of insanity, certain cases are dependent upon removable causes. In illustration he reported four cases in which recovery followed operation. The first occurred in a man, thirty-four years old, who, following a blow upon the head with a brick, suffered from severe headache, and subsequently presented symptoms of insanity. Symptoms suggestive of syphilis also were present. Upon removal of a button of bone from the site of previous injury the dura was found adherent to the bone. The opening was enlarged and the adhesions freed. The patient was also placed on antisyphilitic treatment, and at once improved and continued thereafter in good health. The second case occurred in a woman, fifty-four years old, who, following a blow upon the head with a fist, became violently insane. On trephining at the sight of injury the bone was found greatly thickened, and four ounces of serosanguinolent fluid escaped. The dura was greatly congested. Within a week reason was entirely restored, in two weeks more the woman was dismissed, and six months after the operation was absolutely well. The third case was in a man, twenty-six years old, suffering from melancholia. A strip of bone, one-quarter inch wide, was removed from the left temporal region corresponding to the coronal suture. The last case occurred in a laborer, forty-five years old, who suffered from delusions of persecution, together with severe headache. A portion of skull was removed from the site of greatest pain and the adherent dura freed. In a short while both headache and mental symptoms disappeared. The following conclusions were submitted: (1) Traumatic insanity is dependent upon an appreciable pathologic condition incident to the traumatism and interfering materially with intellectual function. (2) Idiopathic insanity is dependent upon an, as yet, inappreciable alteration of the brain-substance interfering with intellectual function. (3) The relief of pressure by trephining and extensive craniectomy is a harmless procedure. It is a most valuable adjuvant to promote, with the aid of suitable medication, the absorption of deep exudates, and the drainage of fluids from the cranial cavity, which would otherwise be retained and act as irritants.

DR. A. J. DOWNES related the case of a young woman, presenting symptoms of melancholia, who had a scar upon the head corresponding to the site of a previous injury. A trephine opening in this situation disclosed evidences of an old blood-clot, which were removed so far as possible. She recovered from her aberration and in a subsequent attack of typhoid fever was entirely free from delirium.

DR. CHALMERS DA COSTA related that at a time when he was a resident physician in a hospital for the insane, he was impressed with the suddenness with which acute insanities are at times capable of disappearing. He referred to a number of cases in which mental symptoms disappeared following traumatisms and operations upon remote parts of the body. He pointed out that some of the lesions found are not causative of, but secondary to, the insanity. Trephining is justified in cases of insanity only when there is a distinct history of head-injury, or evidence thereof, with persistent localized headache.

DR. J. M. BARTON related a case of insanity in which the mental symptoms disappeared after the removal of a portion of diseased tibia.

J. P. CROZER GRIFFITH reported

A CASE OF VARICELLA GANGRENOSA, DIPHTHERIA, RUBEOLA, AND VARICELLA, OCCURRING AT THE SAME TIME.

The patient was a child, twenty-two months old, whose father was just convalescing from an attack of pneumonia, and looked tuberculous. For five days there had been painful cough, with fever, and rapid and labored respiration, and physical examination disclosed evidences of croupous pneumonia. For several days the symptoms progressed and indications of meningitis made their appearance. The attack had been a severe one and had threatened to be fatal. Resolution, however, finally ensued, and the child entered upon convalescence. After the lapse of more than a week follicular tonsillitis developed, and, upon bacterioscopic examination, proved to be diphtheritic. A few days later the rash of measles appeared, and after a few days more that of varicella. Both of the latter diseases were prevalent in the hospital at the time. The vesicles present underwent enlargement to the size of bullæ, which burst, leaving erythematous areas varying in size from a split pea to a quarter of a dollar. In these ulceration took place, with the discharge of ichor-

ous pus, and over the ulcers crusts formed. At first the trunk and arms were principally affected, but later the head and the legs were also involved. Amid symptoms of heart failure death took place apparently from bronchopneumonia. The most significant feature of the *post-mortem* examination was the presence of diphtheritic membrane in the trachea, with none in the larynx.

DR. F. WOODBURY asked if there were any possible connection between the cutaneous eruption and any drug that had been administered. He referred to a case in a child, in which a vesicular or bullous eruption repeatedly followed the administration of small doses of potassium iodid.

DR. J. A. CANTRELL expressed regret that the name varicella gangrenosa had not been dropped, as a similar cutaneous exanthem may attend other conditions.

DR. W. M. WELCH adverted to the rarity of varicella gangrenosa, and spoke of its occurrence especially in children broken down in health.

DR. W. B. ATKINSON referred to an epidemic which, as a representative of the State Board of Health, he had diagnosticated as one of variola, while the local physicians insisted that the disorder was varicella gangrenosa.

DR. J. F. SCHAMBERG suggested that so-called varicella gangrenosa might be merely the dermic manifestation of a systemic intoxication, such as may appear in connection with any infectious disease.

REVIEWS.

DEFORMITIES. A treatise on Orthopedic Surgery intended for practitioners and advanced students. By A. H. TUBBY, M.S. Lond., F.R.C.S. Eng., etc., etc., illustrated with 15 plates and 302 figures, of which 200 are original, and with notes of 100 cases. Pp. 598. Publishers: The Macmillan Co., 66 Fifth avenue, New York.

IN his preface the author states that orthopedic practice in England does not include all phases of disease of the bones and joints, "on what grounds it is difficult to understand," and, as the title indicates, the scope of the work is limited to actual deformity. The omission of tuberculous diseases of the joints from consideration must impair its value as a text-book in this country, where the prevention of deformity has become of such importance in orthopedic work. Tuberculous disease of the spine is considered at length; preliminary recumbency is the routine practice, while jackets of plaster or felt, fulfil all needful requirements of ambulatory treatment. A Taylor brace of a pattern of thirty years ago is figured, and Erickson is quoted as saying that, while it is of value in advanced deformity, yet its leverage power is so great that it may be a source of inconvenience or danger in early cases; the writer is evidently not familiar with its use. Good results from the expectant treatment of abscesses are unusual, although this may receive a trial in favorable cases; aspiration, simple or combined with injections of anti-tuberculous remedies, is not advised. Psoas and lumbar abscesses should be treated as a rule by the radical methods of Treeves and Barker.

Curvatures of the spine receive full consideration; the treatment recommended is constitutional, postural, and by exercise. Braces are adviced in early cases accompanied by much muscular weakness, and in a stage of marked deformity when pain is a symptom. With treatment of forcible correction the author has had no experience.

The various contractions and bodily deformities, some of which are not often mentioned in similar works, are ably considered. The subject of clubfoot occupies one-quarter of the entire volume.

The writer is in favor of gradual correction of deformity by tenotomy and braces, even in advanced cases, but other methods are fully described.

Although the absence of the confusing variety of the illustrations of braces that often fill the pages of similar works, is not to be regretted, yet if the methods of manufacture and application of those braces used and recommended by the writer had been more clearly described, the practical value of the book to the practitioner unfamiliar with the details of orthopedic treatment, might have been increased.

The book is well written; the principles of treatment are well presented; it shows wide reading on the part of author, and the numerous quotations from American sources give it an air of familiarity unusual in an English book.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 24, 1896, TO AUGUST 17, 1896.

So much of S. O. 69 A. Go. March 23, 1896, as directs First Lieutenant Benjamin Brooke, Assistant Surgeon, to report to the President of the Examining Board, appointed to meet at San Francisco, Cal., April 14, 1896, for examination by the Board, is revoked.

First Lieutenant Henry A. Shaw, Assistant Surgeon, will proceed to Fort Brady, Mich., without delay, and report for temporary duty at that post.

Lieutenant Colonel Alfred A. Woodhull, Deputy Surgeon General, and Major Charles Smart, Surgeon, are detailed to represent the Medical Department of the Army at the twenty-fourth annual meeting of the American Public Health Association, to be held at Buffalo, N. Y., September 15, 1896.

A board of medical officers to consist of Colonel Dallas Bache, Assistant Surgeon General, Lieut.-Colonel William H. Forwood, Deputy Surgeon General, Lieut.-Colonel David L. Huntington, Deputy Surgeon General, Major Walter Reed, Surgeon, Captain Charles M. Gandy, Assistant Surgeon, is constituted to meet at the Army Medical Museum Building on Wednesday, September 23, 1896, at 10 o'clock A.M., for examination of candidates for admission to the Medical Corps of the Army.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 29, 1896.

August 24th.—Medical Director DAVID KINDLEBERGER placed on the retired list September 2d.

Assistant Surgeon H. LA MOTTE ordered to the naval hospital at Norfolk.

Surgeon C. BIDDLE detached from the "Monongahela" and placed on waiting orders.

August 26th.—Medical Inspector J. C. WISE, Surgeons J. C. BYRNES and C. BIDDLE, ordered as a board to convene at Annapolis, September 3d, to examine candidates for admission to the Naval Academy.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXIX. NEW YORK, SATURDAY, SEPTEMBER 19, 1896. NO. 12.

ORIGINAL ARTICLES.

SPEECH DEFECT AS LOCALIZING SYMPTOMS, FROM A STUDY OF SIX CASES OF APHASIA.

BY J. T. ESKRIDGE, M.D.,
OF DENVER, COL.;
NEUROLOGIST TO THE ARAPAHOE COUNTY AND ST. LUKE'S HOSPITALS.

THE various defects in speech caused by lesions of the brain constitute an intensely interesting subject for study, both from the standpoint of the psycho-physiologist and from that of the practical physician, especially the neurologist.

In this paper I shall endeavor to deal with the importance of some speech-defects as localizing symptoms.

In all of the six cases of aphasia that have been reported by me in this journal[1] in connection with the surgeons, Drs. Rogers and Parkhill, who operated upon the patients, the defects in speech were the principal symptoms, and in three of them they were practically the only localizing symptoms. In these three cases, guided alone by the character of the disturbance of speech, I was able to recommend surgical procedures which proved successful in averting fatal terminations.[2] In one[3] of the other cases of the series the symptoms of speech-defect were the only ones present for a time, and were sufficiently marked from the first to establish a diagnosis of organic disease of the brain. At the time of the operation on this case for the removal of the growth from the brain, these symptoms were relied upon to determine the extent and the exact location of the tumor. In the remaining two cases[4] of the series the speech-defects constituted the troubles for which the operations were performed.

The last three cases in the series published presented defects on the motor or emissive side of the speech mechanism. The first[5] of these three is the most interesting on account of the distinctness of the symptoms, the care with which they were observed, and the limited character of the lesion found at the time of the first operation. A detailed description of all the symptoms will be found by referring to the number of this journal in which the case has been published. Briefly stated they were, a loss of the power to spell or to arrange the letters in a word; loss of the power to write intelligibly, because the letters were jumbled together in an irregular manner, but the letters of the alphabet were formed perfectly. In studying his spelling from day to day, it was observed that while there was a certain similarity in the manner in which he arranged the letters in the words he spelled the same word differently from time to time, thus showing an uncertainty in his own mind in regard to how a word should be spelled.

Bastian[1] gives the copy of a letter written him by one of Sir Wm. Jenner's patients while he (Bastian) was a resident physician in University College Hospital in 1869. The recorder states that the handwriting was very good, and that the letter, which is a long one, contained only two trifling erasures. While there are several mistakes in spelling, the principal errors consist in the transposition and omission of words. Unfortunately this case is not given in sufficient detail to enable one to determine whether the defect in writing was due to a lesion in the receptive (sensory) or emissive (motor) side of the speech mechanism.

Kussmaul[2] quotes several cases from a paper written by Bastian. One of these was observed by Hughlings Jackson. In it, the misspelling was the most glaring speech-defect. The patient in attempting to write her name, wrote "Sunnil, Siclaa, Satrena," and for her address, she wrote the following: "Sunesr nut to mer tinn-lain." In another case observed by Bastian, the patient tried to write "Royal naval medical office belonging to the Admirality," wrote "Roydnendd navendendd oforendendd Belondendd." The patient observed by Ferber, an account of whose case is quoted by Kussmaul in this connection, wrote "schrüssen" for "grüssen," "schreigen" for "schreiben," "butter" for "mutter," "omdern" for "modern," and in her own name put a "g" in place of "ch."

In none of the above-quoted cases was the

pathologic lesion determined by an autopsy or surgical operation, and Kussmaul fails to quote the clinical records of the cases to a sufficient extent to enable one to determine the probable seat of the lesion. The spelling, however, in most of the cases is similar to that found in the fourth case of this series. This case, so far as I know, is the first one placed on record in which a lesion limited to the foot of the second frontal convolution has been found, either at the autopsy or by a surgical operation for the relief of the brain symptoms, in which the speech-defects have been observed and studied. The symptoms were carefully observed, and the primary defect in speech seemed to be an inability to arrange the letters in words in the order in which he had learned to place them. The man was intelligent, fairly well educated, and for years had held a responsible position that required him to be accurate in his spelling and writing. The defect in spelling led to his writing in an unintelligible manner. Besides the defect in spelling, there was an inability to arrange the words in a sentence according to grammatical usage, syntactic disturbances in speech or akataphasia.[1] Syntactic defects in speech are found most typically in some cases of sensory aphasia. In the second case published in this series, the power to spell was perfect, but akataphasia was pronounced.[2] (One reason for concluding that the primary defect in speech, in the third case reported,[3] was an inability to spell rather than an inability to write, was the patient's power to write readily and correctly on my spelling out the words for him.) I have a case under observation at present, in connection with Drs. Hopkins and Mager, in which the inability to spell is even more marked than in the case reported in this series. Other symptoms in the case just referred to, point to a lesion in the left frontal lobe, and an operation for the relief of the patient is contemplated as soon as the consent of the relatives is obtained.[4]

Loss of the power to spell correctly undoubtedly occurs in persons who are suffering from sensory aphasia, but these cases are easily distinguished from the cases of aphasia in which no visual or auditory disturbance of speech is found. It is probable that most cases of the loss of the power to spell due to a lesion in the foot of the second convolution will be associated with some impairment of the mind, the degree depending upon the character and extent of the lesion. Further observations are needed before we can determine whether those cases termed dyslogical paraphasia[1] can be distinguished from those forms of aphasia in which the defect in spelling is apparently the primary and principal symptom.[2]

If any conclusion is justified in the observation of one case, it would be that a lesion in the foot of the second frontal convolution on the left side in right-handed persons and probably on the right side in left-handed individuals will give rise to a defect in speech in which the principal symptom will be the loss of the power to spell.[3] It should be borne in mind that a lesion, such as a tumor, abscess, cyst, and probably thrombotic softening occurring in the foot of the second frontal convolution will interfere to some extent with articulation, the mentality of the patient, and in many cases with the function of Broca's convolution. It is probable that the syntactic disturbances in speech depend upon the impaired mental condition of the patient. "Unlike words, sentences are not stored up in memory ready for use."[4]

Does a center for writing exist? According to Bastian and others, cases of agraphia have been observed in which the patient was unable to make more than meaningless strokes. These patients have been unable to read or spell correctly. We can write with a pen held with the teeth, hand, or foot. It is very improbable that the same center in the cerebral cortex would serve to guide these various widely separated groups of muscles in writing. On the other hand, no matter what groups of muscles we employ in the formation of letters, the arrangement of the letters in a given word is always the same. It seems to me more probable that the memory for the arrangement of letters in words is stored up in the cerebral cortex. This process is learned by tedious and repeated repetition. We should naturally expect to find the cortical center in which is registered the memory pictures for the arrangement of letters in a word, to be located near the center which governs the muscles usually employed in

[5] Kussmaul.

[1] The patient was operated upon by Dr. Mager, the left second frontal convolution was found diseased, but the lesion was so diffuse that symptoms of aphasia lost much of their apparent localizing value.
[2] In these cases, if the loss of the power to write is due to the loss of the power to spell, is the word agraphia the proper term? It has occurred to me that the word anorthographia might be employed instead. Professor Maurice G. Dunham, professor of Greek in the University of Colorado, for some very good reasons seems to prefer the term scoliographia instead of anorthographia. The principal objection which he makes to the latter term is the use of the "an" to denote negative. "An" is in common use before arthria to denote the negative.
[3] It is possible that the primary defect is in the inability to pronounce.
[4] Kussmaul.

writing. It will be interesting to observe whether a lesion in the second frontal convolution on the right side of the brain in right-handed persons is attended with any loss of the power in spelling. So far as I can see at present, it is impossible to investigate the orthographic center in a very illiterate person.

Dr. Charles K. Mills has recorded a case of defective speech utterance from orolingual paralysis.[1] In his case, the lesion involved the lower portions of both central convolutions on the left side, the foot of the left frontal escaping almost entirely. Articulation was imperfect, but the patient could talk. In the fifth case[2] reported in this series, there was very decided weakness, in fact, almost complete paralysis, of the orolingual muscles of the right side, and an inability to utter words, except the simplest ones, with sufficient distinctness to be understood. It was impossible for a listener to understand what he read. He could utter monosyllables slowly and with an explosive sound of the lips, so as to be understood after two or three ineffectual attempts. Unfortunately his right hand was at first nearly paralyzed, and after he regained strength in this hand, it was used so awkwardly that his writing was indistinct. The writing with the left hand was no better than with the right. None of the letters were well formed, but there was no transposing or omission of words or letters. There was no evidence that Broca's convolution was affected. His attempt at writing showed no misspelling or agraphia, but rather a disgraphia. The lesion at the operation was limited to the lower portions of the central convolutions (ascending frontal and parietal). This case, as well as the one reported by Mills, points very conclusively to the existence of an orolingual center concerned in speech. It is probable that this center is bilateral, but so far as I am aware, no cases of lesion in the orolingual center on the right side in right-handed persons have been studied and reported.[3] Neither in the case reported by Mills, nor in the one reported by me, was the inability to utter words complete, as we would expect to find if the center is unilateral.

From a study of the symptoms found in these two cases of orolingual paralysis, and from the flattering results of the operation in the case reported by me, it seems to me that we are justified in recognizing an orolingual cortical center which is concerned in speech, and that under certain conditions, operative procedures, when this center is diseased, may be followed by partial restoration of the power of articulation.[1] No further comments on the last case of the series are needed beyond what are made in connection with the report of the case.[2]

Turning now to the cases of sensory aphasia reported in this series,[3] we find in the first[4] that the lesion was limited to the angular gyrus, its subcortical region and the anterior portion of the occipital lobe, that there was a condition of apraxia for all objects except those that were very familiar, and that this existed for all the sense memories. The patient manifested a state of verbal amnesia for all objects save those with which he had been most familiar. There was no auditory disturbance of speech. He could not recognize letters, figures, and colors seen. He could not understand printed and written words seen, nor read inaudibly or aloud. He could not recall objects, the names of which were seen. The power to write voluntarily, at dictation, to copy and to write the names of objects presented to him by the various senses, was at first almost completely lost. He was unable to read. He failed partially at first to write his own name or to read it after it had been written by another. He usually was unable to recognize a letter by tracing it with his finger or pencil, the movements being guided by another; neither could he call up mentally the appearance of an object, figure, letter, or word. He made a partial failure in counting numbers or money. He could not recognize a single card, although he had formerly been very fond of games.

In the third case[5] the lesion was extensive, involving the Rolandic parietal and angular regions and the centrum ovale of these. Apraxia was pronounced; verbal amnesia was present; he copied poorly, but mechanically; recognized a tune, and could sing if some one led; could recognize only a few spoken names; could name any word that was spelled aloud; was unable to read, or to write voluntarily, and could not read what he copied; did not recognize colors, but did objects; could not count in numbers or calculate, but could count money. In the second case[6] the lesion was limited to the posterior halves of the first and second temporal convolutions and the centrum ovale beneath this portion of the

cortex. The patient was mind- and word-deaf; verbal amnesia was present, apparently; there was partial apraxia; he could read, but did not seem to understand; he read aloud so that any one could understand him; he could write voluntarily his name and whisky; did not recognize playing-cards; and copied fairly well, converting printing into script. There was no visual disturbance of speech.

On reviewing the symptoms, we find that all the cases of sensory aphasia presented a condition of apraxia and verbal amnesia, but in none of them were these defects complete. In the two in which the lesion involved the angular region, there were visual disturbances of speech, such as word-blindness and inability to call up mentally the appearance of a word or letter. In the case in which the lesion was limited to the first and second temporal convolutions, there were auditory disturbances of speech, such as mind- and word-deafness at first, later word-deafness and inability to call up mentally the sound of a word or letter spoken aloud. In none of the cases was there an inability intelligently to see objects (mind-blindness). In only one was there hemianopsia, and this occurred in the case in which the lesion penetrated the centrum ovale deeply beneath the angular gyrus. In the case of extensive lesion in the angular region, there was loss of power to read or write, while in the other, in which the lesion was less extensive, but involving the angular gyrus, there was at first an almost complete loss of power to read and write. In the case in which the lesion affected the temporal convolutions, the patient could both read aloud and write, but did not seem able to understand what he had read or written. All the patients could write their names, although it was done imperfectly by those suffering from visual disturbances of speech. None of the three could count in numbers, but one could count money.[1] None could at first play a game of cards. In one, the case with an extensive lesion involving the Rolandic parietal and angular regions, the ability to recognize a word spelled aloud was very good.

We may conclude, from a study of the symptoms presented by these three cases of sensory aphasia, that apraxia and verbal amnesia have no localizing value, except to place the lesion in the sensory or receptive side of the speech mechanism; that inability to count or to play games of cards have no localizing value, as these defects are found in a few cases of motor aphasia; that word-blindness places the lesion in or near the angular gyrus; that word- or mind-deafness is evidence that the lesion is in the posterior portions of the first and second temporal convolutions. In each of these cases the subcortical as well as cortical region concerned in speech was affected.

All the patients suffering from sensory aphasia, with one exception, copied mechanically, transcribing writing into script and printing into printing, giving each letter the amount of shading found in the original, and that all the cases of motor aphasia transcribed printing and writing into script. This seems to be of considerable diagnostic importance in distinguishing the motor from the sensory forms of aphasia.[1]

ENTEROPTOSIS.[2]

BY MAX EINHORN, M.D.,
OF NEW YORK.

ENTEROPTOSIS designates a condition in which the suspensory ligaments of some of the abdominal viscera are relaxed, causing a more or less pronounced descent of these organs.

The disease begins with a prolapse of the intestines, particularly of the right part of the colon transversum, due to a relaxation of the weak ligamentum colico-hepaticum. The colon ascendens and colon transversum, losing their ligamentous suspension, sink down, and so the colon transversum, instead of running straight across the abdominal cavity, runs obliquely from below upward. At the left end, the transverse colon is held in place by the strong ligamentum gastro-colicum. The acute angle produced at this point by the prolapse of the other end of the transverse colon, causes a partial occlusion of the lumen of the gut (enterostenosis). The transverse colon, therefore, remains contracted and empty, and gives the condition described as "corde transverse." Coincident with the descent of the transverse colon, there is a relaxation of the ligaments (mesenteries) of the small intestines, and this produces a dragging down of the stomach, and causes the liver and kidney, through the ligamentum gastro-colicum, to assume a lower position than normal (hepatoptosis and nephroptosis). Thus there may be a prolapse of all the intestines (splanchnoptosis). This enteroptosis causes en-

[1] A little brochure that contains much of deep interest to every student of aphasia has been written by Sigm. Freud, "Zur Auffassung der Aphasien; Eine Stritische Studie," Leipzig und Wien, 1891. So far as I am aware, this little book has not attracted much attention, especially in England and America. The author is at variance with the theories of Wermike and Leichtheim, but the practical results of his conclusions are nearly the same as those of the writers just referred to.

[2] Read before the Fifth District Branch of the N. Y. State Medical Association, May 26, 1896.

terostenosis and increases the specific gravity of the intestines, because they do not contain gas, thus diminishing the abdominal tension. A *circulus vitiosus* is produced which, if not interfered with, grows worse.

The subjective symptoms of this disease are: Weakness and constant feeling of lassitude; difficulty in digestion of fats, farinaceous foods, acids, pure wine, pure milk, with an increase in the digestive troubles about three hours after meals; sleeplessness; usually constipation or irregularity of the bowels.

The objective symptoms, according to Glénard, are: (1) Splashing sound (*clapotement épigastrique*). (2) Pulsation of the abdominal aorta (*battement aortique*). (3) "Corde colique transverse." (4) In the right hypochondriac region, frequently movable kidney.

By the "corde colique transverse," Glénard means that resistance, which is found lying over the aorta from three to five centimeters above the navel, running horizontally from six to ten centimeters on each side of the median line. This gives the impression of a sausage-like body, one centimeter in width, and was supposed by Glénard to be the displaced colon transversum, for pressure on the right iliac region at the beginning of the colon ascendens produced rumbling sounds in the corde transverse.

Glénard distinguishes three different periods of the disease. During the first period (atonie gastrique par entéroptose) the patient eats everything, but experiences slight somnolence or a burning sensation after meals; about 2 o'clock A.M., the sleep is interrupted for a few minutes. Generally there is one evacuation of the bowels in the morning, of somewhat diarrheic nature; there is a gradual loss of strength. In the second period (mésogastrique, gastroptose) the patient avoids fat, farinaceous foods, acids, milk, wine; complains of a sensation of dragging, false hunger, and emptiness about three hours after meals. About 2 o'clock A.M., he remains awake for two or three hours; suffers from constipation, interrupted once in a while by diarrheic evacuations; always feels tired, particularly when arising, and about three o'clock in the afternoon. In the third period (neurasthénique, enterostenose) the patient has lost thirty or forty pounds, and is not sufficiently nourished; he has lived on milk diet, on purées, beef-tea — on most improbable meals; complains of a weighty sensation or cramps in the stomach, and is almost constantly suffering. He does not sleep; the constipation is most obstinate; the daily enemata with difficulty effect an evacuation of fatty scybala, surrounded by mucus or pseudo-membranes from time to time. There is constant complaint of great weakness, so that he hardly leaves the room, and lies on the lounge constantly. He represents the most varied nervous symptoms—cerebral, spinal, sympathetic, both psychical and physical.

As this whole series of symptoms is caused and explained (1) by enteroptosis, (2) enterostenosis, (3) deficient nutrition, the fundamental indications for the successful treatment are pointed out by Glénard in the following way: (1) The intestines have to be raised and maintained in their position. (2) The abdominal tension must be increased. (3) The bowels have to be regulated. (4) The secretions of the digestive tract and of the annexed glands have to be stimulated. (5) The alimentation has to be regulated and the digestion assisted. (6) The organism has to be stimulated. The first two points are accomplished by wearing an abdominal bandage reaching to the navel and exerting a pressure upon the hypogastrium from below upward. This bandage raises the intestines and increases the tension of the abdomen.

To regulate the bowels, Glénard gives his patients, a quarter of an hour before breakfast, any one of the following: Natrium sulphate, 4.0, magnesia sulphate, 3.0, in half a glassful of water, or a teaspoonful or half a glass of Janos; one quarter of a glass of Rubinat; a teaspoonful of Carlsbad salt, or pills consisting of 0.05 extractum rhei. The fourth requirement must be accomplished by massage, electricity, aud lavage of the stomach; and the sixth, by gymnastic exercises.

Glénard first pointed out that the diet should contain plenty of meats, but not of milk, as was formerly customary; frequent meals should be advised, while the quantity of liquids should be greatly reduced.

As has been shown by Ewald, the best sign to recognize enteroptosis, is the demonstration of an existing gastroptosis. This can occasionally be recognized by the splashing sound, which can be produced on the left side of the abdomen over an area extending from the navel, or somewhat above it, down to the symphysis. The inflation of air is another means of detecting the position of the stomach; when the stomach is inflated, the lesser curvature, in cases of gastroptosis, is visible midway between the ensiform process and the navel, or just near the umbilicus.

Gastrodiaphany has been recommended by me as a reliable means of recognizing gastroptosis. It makes the stomach visible as a red zone on the abdomen, between the navel and the symphysis.

To recognize the movable kidney it is only necessary to practise palpation, putting one hand on the back of the patient at the lumbar region, while the other is held flat below the margin of the false ribs, covering the lower outside angle of the abdomen. By having the patient inspire deeply, the kidney, if movable, is felt to slip between both hands; slight pressure with the hand on the lumbar region will facilitate the recognition.

While Israel is of the opinion that on a deep inspiration even a normal kidney may be partly felt by this method of examination, Glénard considers all cases in which the kidney can be detected by palpation as abnormal. He distinguishes four degrees of movable kidney: First degree of nephroptosis: the lower part of the kidney can be palpated during deep inspiration; during expiration, the kidney slips back to its normal place, and it is impossible to prevent its return. Second degree: the greater part of the kidney can be palpated, and it can also be held in its abnormal position, but its superior margin cannot be felt. Third degree: the superior margin of the kidney can be reached on deep inspiration. Fourth degree: the whole kidney is accessible to palpation, even during expiration (the movable or wandering kidney of the older writers). Movable kidney is, according to Glénard, only one of the symptoms of enteroptosis.

It is generally accepted that the corset plays a predominant part in the causation of the downward displacement of the abdominal organs; confinement is also believed to be a great factor. But besides these two points, which refer only to the female sex, there are some other conditions which, likewise, predispose to enteroptosis and are common to both sexes, namely, acute diseases of a grave nature, and protracted ailments accompanied by a considerable loss of flesh.

In January, 1896, I saw 57 male patients with gastric disturbances; among them were 4 with a distinct enteroptosis and right movable kidney (third and fourth degrees); the number of females with the same disturbances amounted to 33, and 13 had distinct enteroptosis with a right movable kidney. April showed similar figures: Number of male patients, 84; enteroptosis with movable kidney, 5; number of females, 59; enteroptosis with movable kidney, 19.

Among the male patients with digestive disorders, the percentage of enteroptosis was 6.2, while in the females with the same kinds of affections, the percentage was 34.8. The great frequency of enteroptosis, which has been stated by Glénard, is fully sustained by the figures just given. Glénard, however, goes too far when he ascribes all digestive disturbances to this faulty position of the abdominal viscera, nor is enteroptosis always the only cause of all the symptoms. According to my own experience, pronounced enteroptosis may exist without any manifestations of morbid phenomena. It is also self-evident that all kinds of gastric affections will occur in cases of enteroptosis as well as elsewhere; for enteroptosis does not afford immunity against digestive disorders. Hence it appears that, aside from the diagnosis of enteroptosis, it is often necessary to recognize the existence of other factors. I must, however, concur with Glénard that in many instances enteroptosis, as such, is liable to produce symptoms, and that these symptoms can be materially improved by the treatment outlined above. The abdominal bandage (which should raise the abdominal viscera) and the restriction of liquids seem to be the most important measures, and should be applied in all cases of this affection.

Meinert[1] examined a large number of young chlorotic girls with regard to the position of the stomach, and found the greater curvature always occupying a very low position (between the navel and symphysis); he concluded that "the gastroptosis" in his cases was the cause of the existing chlorosis. The method which he used to determine the position of the stomach was that of Frerichs; it consists of giving the patient bicarbonate of soda and tartaric acid in two separate portions of water, taken in succession. The carbonic acid gas collecting in the stomach, inflates this organ. The position of the stomach then may be recognized by mere inspection or by percussion. Instead of administering two grams of each of these drugs as is ordinarily done, Meinert gave eight grams. The results this writer obtained do not represent the stomach in its natural state, but in an artificially overdistended condition. Leo[2] and Meltzing,[3] the latter using the gastrodiaphane, refuted Meinert's statement. There is no doubt that Meinert's method of ascertaining the position and size of the stomach is not a very good one, and apt to misrepresent the true condition. Although the occurrence of enteroptosis in chlorosis is quite frequent, Meinert's statement that gastroptosis is a prime factor of chlorosis is not sufficiently proven. Chlorosis is not infrequently met with in

[1] E. Meinert, "Zur Aetologie der Chlorose," Wiesbaden, 1894.
[2] H. Leo, "Ueber Gastroptose und Chlorose," *Deut. med. Woch.*, 1896, No. 12.
[3] Meltzing, "Gastroptose und Chlorose," *Wiener med. Presse*, 1895, No. 30–34.

persons not affected with enteroptosis, nor are all the patients with enteroptosis chlorotic. The corset, upon which a great deal of blame has justly been put for the causation of the descent of the abdominal viscera, and which, according to Meinert, is a great factor in the production of chlorosis, cannot be recognized as a useful and and hygienic garment, and ladies wearing it should, at least, be careful not to lace too tight.

SOME CONSIDERATIONS ON THE TREATMENT OF TYPHOID FEVER.[1]

BY AUGUSTUS A. ESHNER, M.D.,
OF PHILADELPHIA, PA.:
PROFESSOR OF CLINICAL MEDICINE IN THE PHILADELPHIA POLYCLINIC; PHYSICIAN TO THE PHILADELPHIA HOSPITAL.

IT is, perhaps, the repetition of a twice-told tale to present a consideration of the treatment of typhoid fever, but it is because of the perennial interest and the practical importance of the subject that I have ventured to discuss it.

There is no longer any reasonable doubt that typhoid fever is dependent upon the pathogenic activity of the bacillus described by Eberth in 1880, and that it represents the reaction between the body and this microörganism. There are other bacteria—and notably the colon-bacillus—that more or less closely resemble the typhoid bacillus, but each has its distinguishing traits and characteristics, and each its own pathogenic peculiarities. We can thus safely commit ourselves to the proposition that the typhoid bacillus alone is capable of generating typhoid fever, with the corollary that there can be no typhoid fever without the bacillus. This statement implies at once that typhoid fever cannot originate *de novo*—that every case is derived from some preëxisting case. It is of the utmost importance to recognize this truth, as upon its appreciation depends the application of a rational prophylaxis, as well as any hope that may be entertained of the ultimate extermination of the disease. It may thus be confidently predicated that the exercise of a proper care in the disposal of the excreta in every case of typhoid fever would soon lead to the extinction of this disease.

The most common channel by which typhoid fever is conveyed is water used for drinking and other domestic purposes. As a deduction from this fact it may be fairly maintained that thorough sterilization of all water used for these purposes would lead to an enormous reduction in the prevalence of typhoid fever. The transmission may, however, take place, though far less commonly, in other ways, as through direct infection of those in attendance upon the sick, or through the handling of the excreta, the bedding, and the linen of the patient. It is further not impossible that conveyance may take place through the air by means of dried fecal matter reduced to dust.

From the foregoing considerations, it is clear why the intestinal tract generally bears the burnen of the disease, although it is recognized that other structures of the body suffer at the same time, and, in fact, that the intestinal tract may escape, while other viscera are involved. Typhoid fever is thus, like all of the infectious diseases, primarily a local process, becoming soon, however, general. In this connection, two important pathogenic factors must receive consideration. The first of primary importance is the typhoid infection. At the site of original lodgment in the human body the typhoid bacilli, under favoring conditions, undergo multiplication and give rise to the local lesions of the disease. From this point they are often widely distributed throughout the organism, and in this way they may give rise to specific secondary lesions, such as abscesses and inflammations of bone and serous membranes. The second pathogenic factor to be considered is the typhoid intoxication. As a result of the reaction between the invading microorganisms and the tissues of the body, certain poisons are elaborated that are capable of profound activity, as manifested by the general prostration, the delirium, and the pronounced constitutional manifestations. For the purposes of this communication, we shall omit further reference to the purely secondary infections and complications dependent upon other agencies than the typhoid bacillus.

Having thus formulated an hypothesis as to the mode of development of typhoid fever, the question naturally arises at once, How is the disease brought to an end? To this there two ready answers, both of which may be accepted as at least partly correct: In accordance with existing knowledge of the development of antitoxic substances in the course of infectious processes, it may be conceived that the typhoid infection ultimately results in the production of substances inimical to the life of the typhoid bacillus and antidotal to the typhoid intoxication. On the other hand, it is contended that the disease-process comes to an end because of the exhaustion of the pabulum necessary for the continued existence and activity of the typhoid bacillus. The greater significance may be attached to the first.

With these facts before us, the therapeutic

[1] Read before the Delaware County (Pa.) Medical Society, July 24, 1896.

problem is greatly simplified, although we are, as yet unsupplied with the necessary resources for carrying out the plan of treatment thus logically suggested. The remedy is yet wanting that is capable of destroying *in situ* the microörganisms, of inhibiting their pathogenic activity, or of neutralizing the toxins to which they give rise. The experiments in serumtherapy have thus far not yielded results capable of practical application in the treatment of typhoid fever, although it seems not too much to hope that the not remote future will bring a specific remedy for this disease, as well as for other self-limited diseases, one attack of which confers relative immunity from a subsequent invasion of the same disease.

The first important consideration in the treatment of typhoid fever relates to the prophylaxis. With a knowledge of the means by which the disease is most commonly transmitted, it is obvious that its diffusion will be restricted by measures looking to the provision of an adequate system of drainage and of a pure water-supply, and of the application to the individual case of the principles of isolation and disinfection. The preponderant frequency with which the disease is transmitted by means of water—and contaminated milk especially, is an indication for the avoidance of doubtful sources of supply, and, as added precautions, for reliable filtration and sterilization by boiling. Typhoid fever is not, in the ordinary sense of the word, contagious, *i.e.*, transmissible through mere association or contact, although, as has been stated, conveyance takes place through the intermediation of the excreta. Nevertheless, it is the part of wisdom to place the patient in an apartment by himself and have him visited by only the necessary attendants. The ideal mode of disposing of the excreta—including stools, urine, sputum, and sweat—would be their destruction by fire; but a more feasible method consists in their thorough disinfection by means of milk of lime, mercuric chlorid, carbolic acid, and other substances. Corresponding care should be exercised with regard to the soiled body and the bedclothing and apparel of the patient.

When the disease has developed to the point of clinical recognition, there can be no hope of its abortion. It then continues its evolution and pursues its course to the natural termination, unless interrupted by death. Not a little, however, can be done, to mitigate its severity and avert complications, and perhaps, directly or indirectly, to shorten its duration.

Among the many therapeutic measures that have been employed at different times, it may be said of antiseptic remedies, such as carbolic acid, naphthol, salol, guaiacol, etc., that while useful adjuncts, they are without curative or specific effect, and not too much must be expected from them. In their administration, further, care must be taken not to add to the intoxication of an already serious ailment. A similar statement may be made concerning antithermic or antipyretic remedies. In this connection, it is well to bear in mind that even permanent reduction of temperature does not imply dissipation of the disease and its concomitants, for clinical experience has shown that typhoid fever and other infections may exist without elevation of temperature.

So-called expectant treatment is practically no treatment at all worthy of the name, and symptomatic treatment includes only those measures that the conscientious and competent practitioner is always prepared to employ whenever demanded by the exigency.

I have reserved for final consideration the plan of treatment known as the Brand method, the faithful employment of which has resulted in a most gratifying reduction in the ordinary mortality from typhoid fever. Water has long been employed in the treatment of fever, but its methodic use dates back only to 1774, when it received such application at the hands of Dr Robert Jackson, who used warm baths, followed by cold affusions. A little later (in 1777) Dr. Wright used affusions of cold water in the treatment of himself and a companion suffering from a fever. In 1787 the method was taken up by Currie and others, and it soon became a recognized plan of treatment. To Currie belongs the credit of first laying down rules for the methodic application of cold affusions for therapeutic purposes. He recommended this measure especially at the time of the febrile exacerbation, but conceded its usefulness whenever, in the absence of chilliness, the heat of the surface was above the natural and there was no general or profuse perspiration. The temperature of the water ranged from 40 to 70° F., according to season. From this time water continued to be used in a desultory way in the treatment of febrile disorders; but it is from 1861, following the publication of Brand's monograph on the "Hydrotherapy of Typhoid Fever" that the systematic employment of cold water in the treatment of the febrile state dates. The innovation did not escape objection and antagonism, but during the thirty-five years that have elapsed since its introduction it has steadily gained in favor, until to-day it stands as the best treatment of typhoid fever in particular and of the febrile state

in general. Like the treatment of diphtheria with the antitoxin, conviction was in this instance carried also by the "brute force of figures." The method was not attractive in itself, and its application was not unattended with difficulties, but a reduction in mortality among large numbers of cases in the hands of many different observers from figures as high as thirty per cent. to five per cent. and lower could not be viewed with indifference. The method has thus, by its life-saving influence, forced its way into professional favor; but the results secured will depend upon the fidelity with which the details of the treatment are followed, rather than upon the mere use of cold water. Brand's recommendations are, briefly:

Whenever the temperature taken in the rectum reaches 102.2° F., the patient is immersed for fifteen minutes every three hours, day and night, in water at a temperature of 68° F. This is the rule, but it is not an inflexible one, and must be adapted to the needs of the individual case. The object of the treatment is to effect amelioration of the symptoms and to keep the temperature within safe limits. Thus, in an aggravated case, with profound nervous manifestations and hyperpyrexia, the temperature of the water may be as low as 59° F. and the duration of the bath extended to twenty minutes, or even more. When the temperature does not reach quite 102.2° F., it is often useful to bathe the patient for a few minutes once or twice a day at 68° F. or two or three times a day in a half-bath of tepid water (92.4° F.), using also douches gradually reduced to 68° F. In giving the full cold bath, sufficient water is employed to cover the entire body, with the exception of the head, and the temperature is kept down by the constant addition of cold water or of ice. Throughout the continuance of the bath the exposed parts of the body are vigorously rubbed, and from time to time cold water is poured upon the patient's head. Before the bath the patient is given a stimulant in the form of whisky or brandy, and at its conclusion he may be given some warm liquid food or alcohol, or both. Then, without rubbing or other manipulation, he is placed between dry sheets and lightly covered with a blanket. Usually the patient is able to get into and out of the bath without aid, but if the case be asthenic or ataxic, he may be assisted.

The good effects of the bath are seen not only in the reduction of excessive temperature, but also in a clearing of the intellect, a lessening of the stupor, a disappearance of the muscular twitching, a general tonic influence upon the nerves, and especially upon the heart and lungs, in an improvement of all of the bodily functions, in the promotion of sleep, and, finally, in a reduction of the mortality. As a rule, no medication is required, and the use of alcohol is not necessary, except, perhaps, in those who have been accustomed to it. If constipation be present at the beginning, an initial full dose of calomel (gr. viij) may be administered. In the course of the attack simple enemata may be employed.

The hydriatic treatment of typhoid fever may be employed at any stage of the disease and at any period of life. The best results are naturally secured the earlier in the attack the patient is placed under treatment. In cases coming under observation and submitted to the treatment prior to the fifth day, death may be entirely averted. Children bear the full cold bath well. In patients past sixty, it is best to use the gradually cooled bath, the water being at first about 10° F. lower than the temperature of the body, and being gradually reduced in the course of from twenty to thirty minutes, to 68° F. The only complications that interdict the continuance of the baths are intestinal perforation, peritonitis, and free hemorrhage. Experience shows, however, that complications are, in general, less common in those treated according to the Brand plan than in those treated by any other method.

The Brand method finds its widest field of application in hospital practice, but the difficulties that attend its employment in private practice are not insurmountable. The most serious one, besides firmness and resolution on the part of the clinician, is overcome by the construction of portable tubs, some of which can be conveniently folded up and readily transported.

There are, of course, other modes of employing water in the treatment of fever. Thus, we are all familiar with partial baths, tepid or gradually reduced; with spongings with water of varying temperature and with various admixture; as also with the cold pack and with applications of ice, the passage of a stream of cold water through tubes passing over or around to different parts of the body, etc. Martin Barr of Liverpool employs a continuous bath at a temperature of 90 or 95° F., such as in vogue among dermatologists in the treatment of extensive burns of the body. Fenwick of London employs what he designates an ice-cradle, which consists of iron arches fastened to the bed and placed over the patient, from which are suspended zinc buckets, partially filled with ice. Still others have employed evaporating sprays. None of these expedients, however, even approximates in efficacy the Brand plan in the treatment of the febrile state, by means of which, as has been aptly said, severe cases are converted into mild cases, and the classic picture of typhoid fever is no longer seen.

A NEW AND IMPROVED METHOD OF PERFORMING ALEXANDER'S OPERATION.

BY A. LAPTHORN SMITH, M.D., M.R.C.S.ENG.,
OF MONTREAL;
GYNECOLOGIST TO THE WESTERN HOSPITAL, THE SAMARITAN HOSPITAL, AND TO THE MONTREAL DISPENSARY; PROFESSOR OF CLINICAL GYNECOLOGY IN BISHOP'S UNIVERSITY, MONTREAL.

THE more clearly the indications for Alexander's operation are becoming defined the more frequently is it being performed. In the opinion even of those who were at first opposed to it, it is of great value in correcting not only retroversion but also prolapse of the uterus. As long as the uterus can be freely brought forward to the symphysis pubis either by bimanual manipulations, or by the aid of the sound, shortening of the round ligament gives excellent results. It is, of course, unnecessary in temporary or acute cases of retro-

version in which the uterus remains up of itself, or by the aid of an easy-fitting pessary; and it is worse than useless in cases in which there are dense adhesions, unless these latter have first been broken up by the finger introduced through an abdominal or vaginal opening into the peritoneal cavity. There are still, however, many operators of considerable ability in whose hands the operation has proved difficult or even impossible, while in some cases it has been followed by disastrous results. One surgeon, who is afraid of nothing in general surgery, has such a horror of this operation that he has decided never to attempt it again, owing to failure to find the ligaments, even after an elaborate dissection. Another, the pioneer of gynecology and abdominal surgery in Canada, attempted the operation only once but failed to find the ligaments or to sew up the separated pillars of the external inguinal ring, with the result that the woman soon after had two enormous hernias, which she has steadily refused to have sewed up, preferring to exhibit them as a failure of surgery. Many other instances could be mentioned in which operators of the first class dislike the operations, not because they are dissatisfied with the results, but on account of the difficulty and uncertainty of finding the ligaments. The writer in his first few cases had the same experience, having been obliged, in one case at least, to abandon the Alexander operation and perform ventrofixation. It was only after the discovery of the method which will now be described that he has been able to find the ligaments invariably and quickly. After an experience of about forty operations, performed according to this method, he is able to find the ligament and draw it out in from half a minute to a minute and a half. He believes that this method is original, never having seen it described in any of the journals nor witnessed its performance by any operator. It is, however, exceedingly simple and easy, so much so, indeed, that it can almost be performed with the eyes shut, and by the sense of touch alone.

Operation.—The skin is shaved and carefully disinfected in whichever manner the operator prefers. The tip of the left index finger is then pressed firmly down upon the spine of the pubis, when, in many cases, the external inguinal ring can be distinctly felt. An incision directly over this spot is then made, diverging at its outer end about thirty-five or fifty degrees from Poupart's ligament. The incision must go through the skin, superficial and deep fascia, but no farther, and even for fear of severing any of the fibers of the intercolumnar fascia, the last part of the incision should be made with the handle of the scalpel. The pearly, glistening fibers of the external oblique will then be seen, with the intercolumnar fibers running across them, holding the pillars of the ring together. Some fat will appear bulging from between these pillars, and if the finger-tip be pressed upon this fat, the latter will recede into the ring. The secret of success now lies in *not* cutting through this fat down to the spine of the pubis, as Alexander directed, but in keeping it intact, for if this fat be caught up in a Pean's forceps and pulled upon, the round ligament is drawn up. With the tip of the left index finger covering the ring, a pair of closed Pean's forceps is slipped into the canal under the finger and opened, when the only things in the canal, namely, the round ligament and the nerve running with it, are caught by the forceps, and drawn out. All instruments are laid aside, the separation of the ligament from the nerve, and from the fascia which connects the ligament to the canal, being accomplished by the fingers, which are quite strong enough to pick out the ligament, but not sharp enough to cut it. No matter how small the ligament may be at the ring, on drawing it gently out it will be found to be of good size. The ligament is drawn out until the peritoneal covering appears, and this is stripped back with the fingers. The ligament on the opposite side is then found and drawn out in the same way. The ligaments are then anchored in the following manner: While a gentle traction is maintained by an assistant, a fine silk suture is passed through the transparent anterior wall of the inguinal canal, taking in half of the round ligament, and tied. The next stitch takes in Poupart's ligament, half of the round ligament, and then the superior pillar of the ring, and this, when tied, brings the pillars of the ring together as well as attaches the round ligament. If the ring is still too open another stitch may be placed. The wounds in the skin are then brought together by interrupted silkworm-gut sutures. The advantages claimed for this operation are:

1. A one-inch incision in the skin is sufficient.

2. There is no need of dividing the fibers of the intercolumnar fascia, which is the sole support of the external inguinal ring.

3. The round ligament can be quickly found as the natural position of the structures of the ring is not disturbed.

4. The ligaments can invariably be found, although it has been claimed by some that the round ligament is sometimes absent, it is more probable that it is always present, but being split up it be-

comes so weak that it breaks, or, in some cases, some other structure is mistaken for it. There is nothing in the inguinal canal except the round ligament and ilio-inguinal nerve, and if the knife and scissors be laid aside as soon as the deep fascia has been cut through and neither the canal nor the ligament be wounded, then, in grasping whatever is in the canal, we are sure to find the round ligament.

5. By the method above described hernia would be impossible, at least as the result of the operation, for not a fiber is cut that supports abdominal pressure. Even if the woman had a hernia before it would be radically cured by Alexander's operation, performed according to this method. Silk is employed because catgut does not last long enough to give permanent strength to the ring. The one relapse referred to above was due to the employment of silkworm-gut sutures which were only left in two weeks instead of permanently. But in this case there was no hernia.

One cannot but feel sorry to see a good operator baffled by such a small but sometimes difficult operation, but the difficulty is almost entirely due to splitting up the fan-like expansion of the ligament, while following Alexander's directions, which so much reduces it in size and strength that it breaks off when drawn upon. Another source of difficulty comes from what might be called making a false passage by cutting down too freely upon the external oblique, when a little nick is made which may easily be mistaken for the external inguinal ring. A round band of muscle is found in this opening, which is pulled at in vain, for it is a part of the external oblique muscle. When this accident occurs, or, if indeed for any other reason the ligaments cannot be found and drawn out, it is better to leave that side alone for a few minutes and proceed with the opposite side; when, returning to the first side again, the parts will have settled into their normal position, and the real canal will be found.

CLINICAL MEMORANDUM.

REPORT OF A CASE OF ECTOPIC GESTATION ASSOCIATED WITH TUBERCULOSIS OF THE TUBES, PLACENTA, AND FETUS.[1]

BY ALFRED SCOTT WARTHIN, M.D.,
INSTRUCTOR IN PATHOLOGY, UNIVERSITY OF MICHIGAN, ANN ARBOR.

IN so far as I have been able to discover, the case which I present in this report is unique in being the first case of extrauterine pregnancy associated with tuberculosis of the tubes, that has yet been observed. While the field of the etiology of ectopic gestation is thus enlarged by the admission of a new factor, the case becomes more important because of the undoubted proof of the existence of tuberculosis in the placenta and fetus. For this reason its relation to the question of the inheritance of tuberculosis gives the case the greatest scientific interest. This question, still open to discussion, receives here important evidence as to the possibility of the infection of the child from a diseased parent in its intrauterine life.

The patient who forms the subject of this report was from the clinic of Dr. James N. Martin, Professor of Gynecology and Obstetrics in the University of Michigan, and to his kindness and courtesy I am indebted for the history of the case and the results of the operation. The history is briefly as follows:

Mrs. F. C., thirty-eight years of age, had been married for thirteen years. She had had no children and no abortions. Her periods had always been regular until August, 1895. At that time she menstruated in the second week, and then did not have a return until February, 1896. From August to October she felt well, but early in that month she had a sudden attack of sharp and sickening pains low down in her left side. The patient described these pains as darting in all directions, and "feeling as if the navel was being pulled backward." There was a decided tendency to collapse, but the symptoms soon subsided. Two days after she had another, but less severe attack, and six days later she was again attacked with pains so severe that the use of morphin was necessary. After the attack the patient felt very weak and faint; a general peritonitis followed, and it was thought that there was an intestinal obstruction. From this attack she recovered slowly. Four weeks later she had sensations of throbbing, heat, and pain in the pelvis. This was followed by an abundant dark-brownish discharge from the vagina, containing soft, cheesy masses, looking like thick pus. Toward the end of each discharge an offensive odor was noticed. These discharges continued at intervals for about three weeks, being always preceded by sensations of throbbing, heat, and pain. At this time there was passed something resembling a small sack. From the beginning of the trouble the patient gradually declined and lost strength. She could not rest upon either side because of drawing sensations.

Her periods returned in February and again in March. These lasted but one day, the usual duration having been from one and a half to three days. The amount was small and there was much pain. She had also at times a thick white discharge from the vagina, small in amount.

She was admitted to the University Hospital on the 26th of March, 1896. Her general condition at this time was fair, there was a slight anemia; she was weak but not emaciated. Her appetite was fair, but digestion was not normal. The bowels were regular. Her locomotion was not difficult. There were no symptoms on the part of heart or lungs. During the week preceding the operation she had no temperature, and there was nothing in the general aspect of the case to suggest tuberculosis.

The physical examination was made on the 27th. The examination of the heart and lungs was negative. On the

[1] Read before the Michigan State Medical Association, June, 1896.

left side and low down close to the walls of the pelvis, there were dulness and some thickening. The vault of the vagina was tense. The cervix and uterus rested backward, the uterus being immovable, and very sensitive. It measured two and a half inches. At the left of the uterus, extending obliquely outward and upward toward the wall of the pelvis, there was an oval mass, rather irregular in outline and very sensitive. This pushed the uterus to the right, and the cervix somewhat backward. No examination of the blood was made. The urine examination was negative with the exception of the presence of a small amount of pus. Neither this nor the vaginal discharge was stained for tubercle bacilli.

With the exception of the cessation of the menses, the patient had had no symptoms or signs that would lead her to believe that she was pregnant, and she did not think that she was in that condition. The diagnosis of extrauterine pregnancy was, however, made by Dr. Martin, and the patient was prepared for operation. This took place on the 3d of April.

A median incision was made. The parts were found to be very vascular, and there were many adhesions between the uterus, appendages, and intestines. The right tube was found to be tortuous and enlarged, and the ovary cystic. These were removed and the stump cauterized. In the fimbriated extremity was a nodular hemorrhagic mass, about the size of a hazelnut. This was separated during the operation and preserved for future examination. The left ovary was found in about its normal location. It was enlarged and cystic. Above it, and attached to it by many adhesions, extended the thickened and twisted tube which passed upward into a mass about the size of a cocoanut. This mass was covered by friable adhesions, and lay up well toward the intestines. The distal portion of the tube passed into the lower surface of this mass and was lost in the adhesions covering it. About an inch to the right of this the greatly thickened tube was again found and traced on to the uterus, the cyst, therefore, arose from the tube about an inch and a half from this organ. The mass was dissected out with the greatest difficulty. When the adhesions covering the upper surface were removed, the head of a fetus was seen protruding from a rent in this portion of the mass. In removing the cyst the distal portion of the tube, together with the ovary, was separated. These were also removed. The uterine portion of the tube was severed about one-half inch from the uterus, and the stump cauterized. The cyst was then opened in the presence of the class and the fetus demonstrated, but the tubercular nature of the tubal disease was not then suspected. After the demonstration, the specimens were placed in four per cent. solution of formalin and brought to my laboratory.

On the next morning I began my examination of these, with the following results:

Right ovary and tube.—The right ovary was about the size of a small walnut; its surface was slightly nodular. Between it and the tube there was a mass of new tissue, about one-fourth of an inch thick, nodular, and hemorrhagic. From this mass a piece attached to the fimbriæ had been removed during the operation. The cut surface of the ovary showed the usual hyalin and cystic degeneration of the Graafian scars. The gross appearance of the small hemorrhagic mass was so characteristic of the hemorrhagic tubercles of the peritoneum, that it was at once cut and stained. The suspicion was confirmed by the microscopical picture. The mass consisted almost entirely of epithelioid cells; in some portions there was a reticulum of rather coarse connective-tissue fibers. There were also large areas of caseous necrosis, and among the epithelioid cells at the periphery of the caseated areas there were occasional giant-cells with many nuclei. Many of these giant-cells showed beginning caseation. There were but few blood-vessels. Large areas showed extensive recent hemorrhages, while others gave evidence of old extravasation by the large amount of hemosiderin scattered throughout the tissue. Sections of this mass were stained for tubercle bacilli in the usual way, with carbolic fuchsin, and the presence of the bacilli in scanty numbers was demonstrated.

On cutting into the distended right tube it was found to be filled with a soft, cheesy substance, which had not been entirely hardened by the formalin. Smears were made from this and stained for tubercle bacilli, with negative results. Thin transverse sections of the tube were then hardened in absolute alcohol, embedded in celloidin and cut. Some of these sections were stained with the Van Gieson's stain, and others with hemalum. These sections, on examination, were found to give a beautiful picture of tubal tuberculosis. The wall of the tube was much thickened, the vessels were congested, and there were numerous areas of hemorrhage and small-celled infiltration in the connective tissue, and between the layers of muscle. Small miliary tubercles were also numerous throughout the wall and under the outer coat. In many sections the lumen of the tube was entirely filled by a mass of tubercles in all stages of growth, the epithelium of the plications of the mucosa being entirely lost. The tubercles were chiefly epithelioid, with a limited small-celled infiltration around the periphery. In some sections giant-cells were numerous, in others only a few could be found. Extensive areas of caseation with occasional masses of calcification were found in some sections. In others the lumen was only partly obstructed, and numerous small miliary tubercles were scattered through the mucosa just beneath the epithelium, which was preserved. These tubercles were epithelioid, with a moderate small-celled infiltration. Giant-cells were numerous, but caseation was not extensive. Masses of calcification were not uncommon. In many places the folds of the mucosa presented a perfectly normal structure, except for the presence of the tubercles, but in others there was a marked inflammatory process with destruction of the mucosa, and the presence of large areas of small-celled infiltration. Some of these areas were freshly hemorrhagic, others were full of hemosiderin. Toward the uterine end of the tube the process became more miliary in type, and less marked. The sections of this tube stained for the bacilli gave negative results.

Left ovary.—The left ovary was much larger than the right, about the size of a large walnut. The surface was

uneven and covered with the stringy remains of many adhesions which had bound it to the cyst. Many small cysts projected on its surface, and on its upper margin a true corpus luteum presented. The cut surface showed numerous small cysts, hyalin scars, and a true corpus luteum, about three-quarters of an inch in diameter, and of a pale yellow. The convoluted inner margin surrounded a mass of coagulated mucin which was slightly hemorrhagic. The fimbriated extremity of the tube was occluded by a small hemorrhagic mass, and in the fimbriæ were several small cysts and a few small, firm, yellowish nodules. The tube was much distended and twisted, but became about normal in size at the point where it passed into the cyst. On the surface of the tube and ovary there were several small, irregular, brownish masses attached loosely by thin bands of adhesions. Sections of these nodules showed them to be hemorrhagic tubercles of the same character as the one from the right ovary, having the same resemblance to the hemorrhagic tubercles so often found on the peritoneum.

Sections of the distal end of the tube, when examined microscopically, gave a picture similar to that of the right side. There was a miliary tuberculosis of the mucosa, but in some sections the appearance was that of a diffuse process affecting also the walls of the tube. There were large areas of caseation and calcification. Sections from this part of the tube, stained for the tubercle bacilli, gave negative results. The portion of the tube between the uterus and the cyst was also twisted and greatly distended, especially at the point where it passed into the cyst where its diameter reached an inch. It was filled with yellowish material of the consistence of firm cheese. The microscopical examinations of sections taken from this portion of the tube showed a chronic diffuse tuberculosis rather than a miliary process. The lumen was almost entirely filled in some places by a reticulated tubercular mass containing numerous giant-cells; and there were many areas of caseation and calcification. Only a few of the epithelial folds remained preserved. In many places the process extended into the muscular coat, and quite large tubercles were occasionally found there.

Cyst.—The cyst consisted of an outer capsule inclosing the red, spongy, and irregular-shaped mass, which comprised the placenta and the fetal membranes. The outer surface of the cyst was rough, somewhat irregular, and covered with the remains of stringy adhesions. On cutting through the wall numerous yellow areas were found, of varying size, from that of a pin-head to that of a small finger-nail. Some of these were firm, others were soft and cheesy. These masses extended throughout the placenta and fetal membranes. In the cavity of the cyst lay a male fetus, flattened and somewhat macerated, about seven inches in length. Its age was evidently between three and four months, the finger-nails and the glans penis being formed, but the prepuce and scrotum not yet developed. The umbilical cord was about eight inches long, and arose from the lower part of the cyst, very near the large tubercular mass in the uterine portion of the tube.

Fetus.—At about three-fourths of the length of the cord, from its origin toward the fetus, there were several well-marked nodules, one containing yellowish caseous material, the largest one quite firm, except in its center,

[1] Made from formalin-hardened and celloidin-imbedded portion of cord, stained with Van Gieson's stain. Owing to the partial necrosis of the cord it was necessary to greatly overstain in order to bring out the nuclei, the tuberculous area, however, staining much more deeply than the tissue of the cord.

which was soft and yellow. These were cut off for hardening and embedding. The fetus was also opened, and the liver, spleen, kidneys, and lungs, were removed and hardened. These organs were almost entirely necrosed, the liver consisting only of a reddish, cheesy mass, crumbling into bits. Some of the yellow areas in the cyst-wall and placenta were also prepared for examination. The microscopic examination of the sections taken from the cyst-wall showed it to be the greatly distended tube, as the thin layers of muscle could still be detected. The yellowish areas in the wall proved to be giant-celled epithelioid tubercles with calcification. The examination of the similar areas in the placenta showed them to be the same thing. Throughout the whole placental tissue typical tubercles could be found. In one section, stained for tubercle bacilli, their presence was demonstrated.

The tuberculous changes in the placenta could be separated into two groups according to their location, a villous and an intervillous form. In the first the earliest changes took place within the villus itself, the epithelioid cells arising from the connective-tissue cells of the villus, or possibly from the endothelial cells of the placental capillaries, though this could not be shown. Whatever the origin of the tubercle, it is certain that in its development the connective-tissue cells of the villi play the chief part in the production of the epithelioid cells. In those villi in which the process was in an early stage and confined to its inner portion the outer surface remained intact, but with the increased growth of the tubercle this was lost, and the epithelioid cells had broken through into the intervillous spaces. In its further growth the tubercular tissue completely filled these spaces, and in many cases extended around normal villi which stood out sharply against it. The intervillous tubercles were far more abundant than those originating primarily in the villi. In these the first change observed was a proliferation of cells on the surface of the villus at a point where the outer layer of cells could no longer be seen. The connective tissue of the villus, however, presented no change. It is probable that here the epithelioid cells arose from a proliferation of the cells covering the villi. The growth of the tubercle is then outward into the blood-spaces and consists of a proliferation of its own epithelioid cells. This growth, in many cases, was very extensive, filling in completely the spaces between many villi and entirely surrounding them. In many cases prolongations of epithelioid cells could be seen extending out into the masses of fibrin which filled many of the blood-spaces. The areas of caseation were in those parts of the new tissue farthest away from the circulating blood, and, as a rule, the giant-cells lay in the central portions of the mass, and not at the periphery. In some cases the tubercular growth seemed to extend inward into the tissue of the villi as well as out into the blood-spaces. The majority of the villi primarily affected, as well as those surrounded by tubercular tissue, showed more or less degeneration. In many of them the entire outer layer of cells was lost, the connective-tissue nuclei stained very faintly, and there was mucous or fatty change with large

[1] From portion of placenta hardened in formalin and alcohol; cut in celloidin and stained with hematoxylin.

masses of calcification. These changes are all shown in the drawing in which the intervilious form is reproduced.

As to the manner of infection of the placenta, it seems very probable that the bacilli set free from the diseased maternal structures of the tube came with the maternal blood into the intervillous spaces. Here they were deposited upon the surfaces of the villi of the fetal placenta and set up their characteristic changes. As to the primary tubercles in the villi the origin is not so clear. It may, however, be supposed that their production may be due to an entrance of bacilli into the circulation of the villi, and hence into the fetal vessels, at those points where the epithelioid cells have grown into the villus from its surface; and with the caseation and breaking down of the new tissue the bacilli have been set free into the capillaries of the villi, and so could pass into the circulation of the fetus. Since it is definitely shown that the placental tissue has no immunity against tuberculosis, there is no reason to believe that the spread of the process through it would differ in any way from that in any other part of the body.

The sections from the nodules in the cord showed, near the necrosed wall of a large vessel, a loosely reticulated tissue of epithelioid cells and small-celled infiltration. No giant-cells were found, but the character of the tissue with areas of caseation marked it as undoubtedly tubercular. The microscopical examination of the internal organs was negative. The liver consisted almost entirely of formless dead matter. Hundreds of sections of this were stained for the bacilli with negative results. It is greatly to be regretted that we did not recognize the existence of tuberculosis before the specimens were put into the formalin, as the presence of bacilli in the internal organs might have been shown by injecting animals with portions of the organs, or by making cultures from them. Only in the lung was anything like a tubercle found. On cutting this organ, after hardening preparatory to imbedding, two whitish areas about the size of small pin-heads were seen. On section these proved to be two small areas of complete necrosis where the structure was lost, while the tissue about showed faintly staining nuclei without this loss of form. These were, therefore, very highly suggestive of miliary tubercles, but the fact could not be positively decided. One of my assistants thought that he discovered tubercle bacilli in a section of the kidney stained for these, but when I went to look at them they could not be found. Therefore, so far as the fetus is concerned, the actual demonstration in its structures of tubercular changes must be confined to the membranes and cord, but it seems almost certain that the internal organs must have been similarly affected, though this could not be demonstrated beyond all doubt.

The patient died of general peritonitis on the 13th of April, ten days after the operation. An autopsy was refused, so the existence of tuberculosis in the other organs could not be ascertained. As mentioned before, there were no signs or symptoms which would lead us to suspect any other localization of the disease, so that I think the case may be looked upon as a primary tuberculosis of the genital tract. From a sister of the patient it was learned that a year and a half ago the latter's husband had been ill with fever, night-sweats, general weakness, and loss of flesh, and was on this account thought to have consumption, but he afterward entirely recovered. The family physician, in answer to my letter of inquiry, informed me that the husband is now perfectly well, without signs or symptoms of tuberculosis. Specimens of his urine, which were sent to me for examination for tubercle bacilli, have not arrived, so I have been unable to throw any definite light upon the etiology of the patient's condition, or to establish any relation between it and her husband's symptoms of a year and a half ago.

In conclusion, tuberculosis of the tubes, it seems to me from this case, must be considered as an etiological factor in the production of ectopic gestation. If the obstruction of the tube hindering the progress of the ovum toward the uterus is the chief factor, we have in the almost complete obliteration of the canal by the numerous miliary tubercles in the mucosa, a most favorable condition for its occurrence. It is very probable that the salpingitis which is found to exist in almost every case of extrauterine pregnancy, and which is usually looked upon as the causal factor, may, in more cases than is now suspected, be found to be tuberculous.

Up to a very short time ago, tuberculosis of the female genital tract, though it had been known to exist for a long period of time, did not assume that importance which it is now beginning to hold. During the last three years it has been shown that far from being a rare disease, it occurs in a very large proportion of all the cases treated for inflammatory disease of this tract. Williams, of Johns Hopkins, in a very exhaustive article in the "Johns Hopkins Hospital Reports for 1892," reviews the subject up to that year. He makes the statement that in his own experience, about eight per cent. of all the cases in which the appendages are removed for inflammatory disease are tubercular; in other words, every twelfth case of adherent tubes and ovaries, or pus-tubes, is of tubercular origin. He further emphasizes the difficulty of making a microscopic diagnosis. Of his cases only twenty-five per cent. were suspected tuberculosis, seventy-five per cent. being unsuspected as far as this condition was concerned. Since the ultimate diagnosis is, therefore, a microscopical one, it is very probable that a wider experience in making these examinations will increase greatly the proportion in which it is found to occur. The importance, on this account, of a technical examination, as a matter of routine, in all of the cases of tubal inflammation, cannot be too strongly urged.

Tuberculosis of the ovary is not so common as that of the tubes, but still occurs so frequently that it cannot be looked upon as a rare condition. It is most frequently met with on the surface of the organ, but Williams and numerous other observers have found it in the body of the ovary, even in the walls of cystic tumors. With it there is usually found a tuberculosis of the tubes or uterus. In our own case the small nodules attached to the surface of the ovary are really tubercles of the peritoneum. It is here worthy of note that tuberculosis of the tubes must be looked upon as perhaps the most important factor of infection in tubercular peritonitis. It is due largely to the fact that laparotomy has lately been so extensively adopted

as a cure for this condition that the occurrence of tubercular salpingitis has been discovered to be of so frequent occurrence, since in the majority of cases the conditions have been found to be coexistent. The small nodules that were found in this case may, I think, be looked upon as an early stage of tubercular peritonitis in which the infection undoubtedly arose from a diseased tube. The location of the tubercles upon the surface of the ovary and in the fimbriated extremity all point strongly to this mode of origin. It should be mentioned here, however, that some authorities believe the tubal disease to be always secondary to that of the peritoneum, the tube taking in the bacilli from the peritoneal cavity.

Up to the date of Williams' article in 1892, only one case of tuberculosis of the placenta had been reported, and from the description given of that case its nature is somewhat doubtful. But F. Lehmann, in 1893 (*Deutch. med. Wochenschr.*, 1893), found typical tubercles in the placenta of a woman dying from acute miliary tuberculosis in the seventh or eighth month of pregnancy. Schmorl and Kockel, in 1894 (Beiträge v. Seigler, xvi, 1894), also made a report upon this condition, so that this is the third instance in which placental tuberculosis has been reported. Schmorl, Birch-Hirschfeld, and Landouzy, had, however, demonstrated the presence of the tubercle bacilli in the blood of the placenta and of the fetal organs, and were able to make cultures and successful inoculations with material from these organs. Histological changes were not definitely ascertained by these investigators.

The presence of the tubercles in the umbilical cord makes the case important, because it is the first one reported in which that condition has been found. This gives added evidence to the still-mooted questions of the inheritance in the child of tuberculosis from the mother. I regret deeply that I could not satisfy myself as to the presence of tubercle bacilli in the internal organs of the fetus, as it seems almost certain that they must be present.

The cases mentioned above, in which the presence of the bacilli was demonstrated in the fetus, were all cases of acute miliary tuberculosis, the mother dying in pregnancy. It seems very improbable that infection of the fetus in this disease can play much part in the inheritance of tuberculosis because of the death of parent and child before birth occurs. It would be more important to prove the possibility of infection from a localized tuberculosis of the tubes or uterus in which condition the fetus might go to full term and delivery, and so come infected into the world. This case, I think, goes very far toward proving the possibility of this event.

MEDICAL PROGRESS.

Vaginal Disinfection.—The disinfection of the vagina before the birth of a child has been discarded in many lying-in hospitals, and it has been widely claimed that such previous disinfection was a positive danger on account of the possibility of carrying germs from the external genitals into the vagina to set up puerperal fever. AHLFELD, who has recently published "*Ante-partum* Vaginal Disinfection" (*Deut. med. Wochenschr.*, 1896, No. 13), an elaborate statistical comparison of the results obtained in the different maternity hospitals of Germany, attacks this view, the correctness of which is not sustained by his figures. Reckoning only normal labors, the lowest mortality percentages were obtained in Würzburg, Marburg, and Halle, these hospitals having respectively 0, 28, and 48 deaths per hundred thousand, *i.e.*, an average of 0.014 per cent. In all of these hospitals vaginal disinfection is employed, and in no other hospital has such a favorable result been obtained.

General Suppurative Peritonitis Cured by Laparotomy.—Suppurative encysted peritonitis is often caused by laparotomy, not so the generical purulent form. JABOULAY (*Province Médicale*, May 2, 1896), has operated upon thirteen cases of the latter, with three successes. The general condition of the patient was good in every case which had a happy termination. The operation consisted simply in opening the peritoneum and draining it by several rubber tubes. Manipulation of the intestines was carefully avoided, and no lavage was employed. The wound was lightly stuffed with gauze and left open. This same course of procedure was adopted in all cases, however caused, and even in the presence of fecal matter.

THERAPEUTIC NOTES.

Sarcoma of the Skin Cured by Arsenic.—A case of sarcoma of the nose, with secondary nodules in the face, treated by POSPELOW (*Arch. f. Dermatol. u. Syphilis*, vol. xxxiv., part 2) with large doses of arsenic (up to three-fifths grain daily) for a considerable period. The tumors entirely disappeared, and two months later had not recurred. The author expresses himself as in no way certain that recurrence will not yet take place. He warns others against too early abandonment of the treatment in similar cases, as very large doses must be given for two or three months, at least, before a result is looked for. The character of the tumor was in this case determined by histological examination.

Local Treatment for Neuralgia.—SABBATINI recommends as an application in neuralgia:

℞	Menthol } aa Guaiacol }	. . .	3 i
	Alcohol. absolut.	. . .	3 xviii

A dram of this mixture is to be rubbed lightly into the affected part two or three times a day. In the intervals a cotton dressing is employed.

Pruritus Vulvæ Cured by Cleanliness.—In a paper recently presented to the Gynecological Society of Berlin, RUGE (*Berlin. klin. Wochenschrift*, June 22, 1896) insists on the importance of cleanliness in pruritus vulvæ. The disease is almost always purely local, and a thorough cleansing of the genitals, externally and internally, with soap and hot water will remove the germs, and so cure even the worst cases, almost without exception. In gonorrhea a similar treatment is beneficial.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

THE OPTICIANS AS OPHTHALMOLOGISTS.

AN effort was made during the last session of the New York Legislature to pass a bill entitled "An Act to Incorporate the Optical Society of the State of New York, etc." This objectionable measure was discussed at the time in the columns of the NEWS, and the efforts of its promoters were defeated. But as it bids fair again to engage the attention of the Legislature during the coming winter, it seems appropriate to consider the merits of the case as set forth in a recent issue of the *Optical Journal*. The writer says: "It is now pretty generally conceded among oculists, opticians, and the public, that the time has arrived when the practice of adapting glasses to the sight should be regulated by law."

This is an admission we are pleased to note, but the question naturally arises, is there any reason for more laws on the subject? Those already existing seem to cover the ground sufficiently, and define plainly enough who shall practise medicine in the State.

By their provisions some people, not physicians, are exempt from the application of the Medical Act, namely, manufacturers of artificial eyes, limbs, and orthopedic instruments or trusses, and in fitting such instruments on persons in need thereof. But it does not exempt any class of men who fit eye-glasses, and, as the fitting of eye-glasses for the relief of headache, neuralgia, or any reflex due to defective vision is practising medicine quite as much as the giving of remedies of any kind for the relief of any of the ailments to which flesh is heir, it seems as if the adapting of glasses to the sight were sufficiently regulated by law at the present time.

Admitting the truth of this argument, it follows then that the remaining portion of the article above quoted loses whatever force it would otherwise have. For instance, it goes on to say, "At the present time, physicians and opticians alike are lawfully engaged in the practice of optometry. . . . Therefore, any legislation which would interfere with such vested rights, would not only be cruel and unjust, but also unconstitutional."

If the opticians have been *lawfully* practising optometry, as the gentleman puts it, what is the use of complaining at all; why do they not go on quietly practising it and say nothing about it?

The truth of the matter is that the practice of optometry by the optician is an invasion of the prerogatives of the medical practitioner, and is therefore not lawful.

The fitting of glasses in hypermetropia, myopia, and astigmatism, the discrimination between amblyopia without optical lesion and that due to disease, the determination whether muscular defects are due to refractive errors or to grave spinal lesions, all these and many more tell us plainly that the fitting of glasses to the eyes should be in the hands of the physician alone, whose medical education and training make him competent to deal with these questions, which even to his mind are sometimes difficult, if not impossible, to solve.

The adjusting of spectacle frames, the proper centering of lenses, and many of the details of the optician's calling, necessitate experience and knowledge, as much as the compounding of prescriptions for drugs. If the opticians would confine their efforts to perfecting their ranks in this particular, we feel confident that the coöperation of the medical profession would be theirs.

It is a simple matter to talk of the "vested rights" of the opticians, but they have no rights that are greater than the vested rights of citizens generally, and efforts to obtain "rights" that would be detrimental to the public weal ought never to meet with success, nor will they in this particular if the profession will assert its rights, insisting as a necessary requirement of all who desire to become practitioners in any sense, that they comply with the laws govering medical practice.

RECENT PROGRESS IN GYNECOLOGY.

SURGICAL TREATMENT OF RETROVERSION OF THE UTERUS.

Probably no department of gynecology has received so much attention as displacements of the uterus, and of these, retroversion has been the most important. This condition was one of the earliest to attract the attention of the specialist, and received its due share of attention in the way of treatment by tampon and pessary. The next step in the evolution of the treatment, was the introduction of operative procedures. These consisted in plastic work, which aimed at the restoration of the floor of the pelvis, and the reëstablishment of the integrity of the vaginal walls. This departure from tampon and pessary, necessarily implied a lack of satisfaction in the efficacy of their use; but, while it recognized the wisdom of operative interference, it was itself founded upon a false principle. This error consisted in the assumption that the support of the uterus came from below.

Nature's plan of sustaining the various organs of the body in their respective positions, is that of suspension by ligaments. The brain, the heart, the lungs, the liver, spleen, kidneys, all are suspended by ligaments from above. The uterus, being the lowest organ in the body, was supposed to rest on the floor of the pelvis, and, therefore, offered the only exception to the rule of suspension. The inadequacy, however, of all operative procedures for the restoration and building up of supports in the parts below, eventually opened the eyes of gynecologists to the fact that the uterus had ample ligaments to sustain it in place, even when the perineum was entirely obliterated, and the question arose, why then should not the uterus be amenable to the systematic plan of nature, and depend on its ligaments for position and support? This was a question whose answer came with the asking, and malpositions came to be recognized as the result of relaxation in the uterine ligaments. The corollary to this was: In case of misplacement, restore your ligaments, and suspend the uterus. All the various procedures that have been suggested since that time, are but the application of this one predominating principle. Out of it came all the various operations for shortening the round ligaments, as well as the various methods of hysterorrhaphy.

But modify these operations as you may, both of them have failed to quite reach the mark of an ideal operation, and involve many serious objections. Alexander's operation is only applicable to cases in which the uterus is movable. Hysterorrhaphy converts a retroverted organ with adhesions to an anteverted organ, but with adhesions. Gynecologists, generally, now recognize anteversion as the normal position of the uterus. They also recognize the fact that if that position can be maintained, the force necessary to support the organ is reduced to a minimum. Through the facility gained in vaginal work by vaginal hysterectomy for cancer and fibroid tumors and the operations upon the appendages, came the suggestion of relieving retroversion by operative procedure through the same route. This was put into practical application by Mackenrodt and others, in the operation known as vaginal fixation. While this operation restored the uterus to its normal position, and relieved all symptoms, it was found by several German operators to bring more or less serious complication and disaster in those patients who became pregnant. The advantages to the patient of this procedure over Alexander's operation and abdominal fixation, were so apparent that those who had tried it were little inclined to surrender these advantages, without serious effort to so modify the operation that the unfortunate consequences might be averted. Mackenrodt's original operation, briefly stated, consisted in making an incision through the anterior wall of the vagina, and dissecting the bladder from

its attachments to the uterus, anteverting the uterus, and stitching its anterior wall directly to the edges of the vaginal incision. This procedure carried the fundus too low in the pelvis, and held it so firmly that in those cases where pregnancy occurred the anterior wall was prevented from taking its due part in the normal expansion of the uterus, and the fundus from properly rising out of the pelvis. It quickly became apparent that this difficulty might be overcome by allowing the uterus more freedom of motion, and various suggestions have been offered for accomplishing this object. The latest modification of the operation, and one which commends itself more fully than any other, has been suggested by Wertheim (*Centralblatt f. Gynäk.*, 1896, No. 10). His method consists in utilizing the round ligaments for attachment to the vaginal wall. After incising the vagina and dissecting off the bladder the finger is slipped over the fundus, the round ligaments are hooked up at a reasonable distance from the horn of the uterus, and attached on either side to the borders of the vaginal incision. The immediate results of the operation are excellent, but as no case of pregnancy after the operation has been reported, the crucial test of its value has not yet been applied. It seems reasonable to expect, however, that with the freedom of movement thus allowed the uterus the unfortunate consequences attending Mackenrodt's operation will be absent. It is also still uncertain whether the position will be maintained after parturition. If this shall prove to be a permanent relief of the displacement, and free from the disasters of Mackenrodt's method, it will score a great advance over both the Alexander operation and abdominal fixation.

A more careful analysis of the supports of the uterus points to the utero-sacral ligaments as a simpler and, from an anatomical and dynamic standpoint, more perfect means of retaining the correct posture of the uterus. When a woman is in the erect posture the uterus lies normally upon its anterior face; and if the cervix can simply be held sufficiently high in the hollow of the sacrum, gravity will carry the fundus to the front. The tissues that accomplish this are the utero-sacral ligaments. In all cases of retroversion, these ligaments must relax sufficiently to allow the cervix to descend in the pelvis before retroversion can occur. If, then, these ligaments can be made sufficiently taut to maintain the cervix at its normal level, the uterus must perforce be held in a position of anti-version. When these ligaments have become elongated, the indication would seem to be to shorten them. This principle has been applied recently by Gottschalk (*Centralblatt f. Gynäk.*, 1896, No. 16) in two cases, with perfect result. Briefly stated, his technic consists in catching the utero-sacral ligaments, after opening Douglas' pouch, near their attachment to the sacrum and stitching them to the posterior surface of the uterus, just above the vaginal attachment. The success of Gottschalk in two persistent cases of aggravated retroversion invites further trial of this procedure. The principle is undoubtedly correct. The method allows of thorough and careful treatment of the appendages, and therefore is the most perfect one yet suggested for dealing with retroversion.

ECHOES AND NEWS.

Killed but not Struck by Lightning.—Globular lightning set fire to a woman's dress, near Angers, France, the burns causing her death soon after.

Another Use for the X-ray.—A German observer points out that by the use of the X-ray, brick-dust can be traced in Cayenne pepper, sand in spices, and chalk in flour.

A Remedy for Depopulation.—As a means of stopping the depopulation of France, Dr. Janel, in a paper read before the Academy of Medicine, proposed to throw the burden of taxation from large families on to the rich.

The Amherst Infirmary.—The new infirmary at Amherst College, the gift of George D. Pratt of Brooklyn, will be erected by a Boston firm, and is to be completed on March 1st next. It will cost $17,000.

Quinin-growing in India.—The Government has declined to accede to the request of the private growers of cinchona that the Government plantation shall be discontinued and all supplies taken from the private growers.

Lunacy in Scotland.—The number of lunatics in Scotland for 1896 is 14,093, while in 1858 it was 5824. This is an increase of 142 per cent. The population has increased only 38 per cent. during the same period.

Fatal Case of Nose-bleed.—Julius Gottlieb, a law student, who had been affected with nose-bleed for about three weeks, died at Mt. Sinai Hospital, New York, September 12th. The cause of his death was pernicious anemia.

Two Insect Terrors.—An employee on a Mississippi steamboat died in great agony from a mosquito bite over the right eye. A ten-year-old boy of Marion County, Kan., was recently kicked in the eye by a grasshopper and the sight was immediately destroyed.

The Dangers of Decomposing Organic Matter. — The medical officer of health reported to the Tavistock, England, District Council several cases of diphtheritic croup, which had their origin in some children playing with the decomposing carcass of a sheep.

Floating Hospital Trips.—Forty-six thousand two hundred and fifty-three women and children were carried on the New York Floating Hospital during the season of 1896, which closed last week. Over 700 cases of severely ill children were treated in the wards without a death taking place on board.

Sanoform.—A substitute for iodoform has been introduced under the name of sanoform, by Gallinek and Courant. It is a bi-iodate of the salicylic methyl ether, without smell or taste, and unaffected by light. Being easily soluble in ether and vaselin it can be used like iodoform, in gauze, collodion, or ointments. It is a powerful desiccator, and prevents the decomposition of discharges.

Bicycling for Women Commended. — The Congress of Sanitary Institutes, which has been in session at Newcastle, England, has strongly endorsed bicycling as being the means of banishing a vast number of the derangements of women, and expressed the conviction that the average standard of the health of women bicyclists has undergone an appreciable elevation.

For a Biological Station.—The Hull gift of $1,000,000 for biological laboratories for the University of Chicago, has been supplemented by the proffer of $500,000 worth of property for a biological station. The donors are Mrs. Edward Roby, E. A. Shedd, and C. B. Shedd. The University will be enabled to control all the land and water it desires of the three thousand acres around Wolf Lake and the channel connecting it with Lake Michigan. Most of the necessary buildings for dormitories will also be given if the offer is accepted.

An X-ray Reform.—The Queen of Portugal, who is celebrated as a pursuer of the various fads of the hour, has been experimenting with the so-called X-ray. She has detailed the ladies of her court to serve as subjects, and has been making pictures of their skeletons. It seems that these gave such an alarming insight into the distortion wrought by tight lacing, that the female nobility of Portugal rushed to order gowns six or eight inches wider in their belt measure. It would be a curious instance of the unexpected turns of human affairs if tight lacing, denounced in vain by medicos and moralists, should finally be suppressed by Dr. Röntgen's invention, and fashion should turn to the Venus de Milo as her ideal of figure.

The International Congress of Psychology.—The third Congress of Psychology was held in Berlin, August 4th to 9th, under the presidency of Professor Stumpf of Berlin. Professor Flechzig, in a paper on association-centers, concluded that the frontal region of the brain is the location of associations of a higher and more abstract kind, and that in the region back of the motor, extending to the visual center in the occipital region, is a great center for the associations which bind the sense-functions together. Professor Lippe, in a paper on the unconscious in psychology, arrived at a return to the soul-substance theory—a hidden thing in which mental states, and especially tendencies of an active kind, may be preserved when we are not conscious of them.

Brooklyn's Supply Ponds to be Cleansed.—Brooklyn officials are working to remove the cause of the impure water that is being furnished to the residents of the city. The mains are flushed every day, some of the officials thinking the cause of the contamination is in the water mains, and not in the supply ponds outside the city. A careful analysis of specimens of the water derived from the various sources of supply shows that it contains no element which, in its present form, may be regarded as being deleterious to health. Engineer De Verona said the ten ponds that supply the city with water, are being carefully watched, and he does not think there will be any contaminating elements introduced into the supply from these sources. The ponds are to receive a thorough cleansing.

Obituary.—John C. Dixon, M.D., of Candor, N. Y., died August 8th, aged sixty-four years. He was a graduate of the Albany Medical College.—Emanuel F. Gerhard, M.D., a junior practitioner at Norristown, Pa., and an alumnus of the Jefferson Medical College, class of 1884, died August 13th, aged thirty-eight years.—James Northrup, M.D., a graduate of the old Geneva Medical School (now extinct) in the year 1857, and a physician of Woodstock, Ill., died August 8th.—William W. Waring, M.D., of Upper Marlborough, Md., died August 5th. He was a graduate of the University of Maryland Medical Department, in the year 1869.—George Dederick Holsten, M.D., of Brooklyn, died at Beaumaris, Ontario, Can., on August 21st, after an illness which had lasted more than three years. He was born in New York in 1857, and graduated in 1882 from the University of New York. Subsequently he became a specialist in dermatology, and won much success in his chosen line of work. He was president of the Brooklyn Dermatological Society, and editor of a paper devoted to the interests of the science.

Typhoid at League Island.—A report from Surgeon Siegfried of the battleship "Massachusetts," says that on August 31st he was compelled to transfer from the ship to the Brooklyn Hospital the fifth case of typhoid fever since that vessel was commissioned at League Island, June 10th, last. It appears that the battleship "Indiana," also fitted out at League Island, has also had sixteen cases of typhoid fever aboard in her very brief career. One of the "Massachusetts'" men died shortly after the vessel left the yard. The surgeon attributes the disease to the bad drainage of Philadelphia, and the condition of that part of the city nearest League Island, and recommends that no ships be commissioned or fitted out there until the conditions are changed. Surgeon General

Tryon, in his indorsement of the report, corroborates the statements, and adds that the four cases of typhoid which developed this summer on the "Bancroft," were directly traceable to the Schuylkill water supply. It is stated at the Navy Department that the "Dolphin" invariably develops cases of malaria after leaving the Washington yard, which is at a focus of sewers.

The Hygienic Value of Fruits.—Dr. Dupoury, in a Paris journal, divides fruits into five classes, each of which possesses a special hygienic value—the acid, the sweet, the astringent, the oily, and the mealy. To the first, including cherries, strawberries, raspberries, gooseberries, peaches, apples, lemons, and oranges, he accords great merit. Cherries he prohibits entirely to those affected with neuralgia of the stomach. Strawberries and raspberries he recommends to those of bilious, plethoric, and gouty temperament, and denies them to those in whom diabetes is present or suspected. Of the sweet fruits he considers that plums are of special hygienic value, and even a preventive in gout and articular rheumatism. He is an ardent advocate of what in Europe is called the grape-cure, in which grapes for several days form the exclusive aliment. The patient begins with the consumption of from one to two pounds daily, with a gradual increase to eight or ten pounds. After a few days of this diet, a marked improvement in the general health is noticeable. The appetite improves, the digestion becomes easy and rapid, and increased capacity to withstand the fatigue of outdoor exercises is noticeable. The grape-cure is particularly recommended to the anemic, dyspeptic, and consumptive, in diseases of the liver and in gout.

The Possible Individuality of Atoms.—Mr. Baly has recently published his conclusions on the two-fold spectra exhibited by oxygen and nitrogen. The popular persuasion is that all the atoms of a particular element are exactly alike. Gaseous molecules are free to move in any direction, and when gas or vapor is rendered luminous, as by passing an electric spark through it, unlike an incandescent solid or liquid, it does not give a continuous strip of color in the spectroscope, but a number of bright lines at intervals separated by dark gaps. If, while the bright lines are being observed, a beam from an electric light or limelight is directed toward the spectroscope, they are seen as dark lines upon the ribbon of variegated color, which distinguishes an incandescent solid. The change is supposed to be due to the absorption by the gaseous molecules of light of certain definite wave-lengths. Mr. Baly's observations go to show that the variability in the spectra of oxygen and nitrogen is due to some profound difference of condition in the gas under different circumstances. For the gas that collects about the point whence the sparks leap across the containing vessel, after a little while is slightly dimmer or lighter than at the other. One of two results must follow: Either those gases (oxygen and nitrogen) are not elements, or there are two kinds one with an atom a little heavier than the other.

"The Great Sin of Great Cities."—The correspondent at Rome, Italy, of the London *Lancet*, August 29th, considers, under the above caption, the question of the alleged increase, in that country, of venereal disease. He says: "Prostitution is a growing evil in Italy, and its Nemesis, syphilitic disease, is correspondingly on the increase. Attempts to control it are made from time to time, but hitherto with the result of driving it more and more into clandestine channels. The sanitary vigilance enforced against it and its pathological sequelæ thus loses in efficiency, till venereal maladies of every kind are becoming a formidable menace to the public health. In these circumstances, the Prime Minister, the Marchese di Rudinì, who also holds the portfolio of the Interior, has addressed a circular to the prefects throughout the kingdom, calling upon them to enforce the regulations imposed by law for the surveillance of prostitution and its victims. In a country like Italy, where, even in the army and navy, the regulation diet is none too generous or sustaining, the diffusion of such maladies is a public disaster, the low resisting power of the people not only favoring lesions of a kind unknown in better-fed communities, but depressing the standard of health by hereditary deterioration. The gross negligence with which the inspection of prostitutes was quite recently practised in garrison towns (Ravenna had an unenviable notoriety among these) compromised seriously the efficiency of the troops already exposed to unsanitary conditions, inducing frequent illness, and even premature breakdown."

CORRESPONDENCE.

CONFIDENCE MEN IN OHIO.

To the Editor of THE MEDICAL NEWS:

DEAR DOCTOR.—On or about the first of February last, a tall, well-built man, about thirty-five, smooth, forcible, but rather repulsive talker, a sort of "hail fellow well met," wearing a forced scowl, came into my office and introduced himself as Mr. Conway, representing Geo. A. Parker, Sons & Co., Local Reference Exchange, head office for New England, Boston, Mass., an organization for collecting accounts, especially old accounts. A small, rather slender young man representing himself as Mr. Conway's brother, and a tall, slender, dark-haired young man, whose name I do not know, were here with him, helping him work the town.

They established a local office here, and got nearly 250 of our best business and professional men to subscribe, and give their notes for $20.00 each, payable six months after date. My faith being good in this Mr. Conway's representations of his plan and work, I unwittingly gave him a good recommendation.

But recent developments lead me to recall that recommendation, as the concern is not worthy of such confidence. I have twice written to and asked this Mr. Conway to return my letter, to which he has seen fit to give no attention. Therefore I take this opportunity of protecting myself against any further influence that document may have, and warn at least my professional brethren against subscribing to the concern, for his statements are misleading, unreliable, and not worthy of confidence.

On inquiry, the Chief of Police of Boston, Mass., recently informed me that there is no such firm or concern as Geo. A. Parker, Sons & Co. Local Reference Exchange, in the city.

These parties agreed to send a letter every ten days to each debtor until five letters had been sent, then if payment had not been made, to sue the accounts and advertise the judgments at five hundred different places over the city. Nearly six months elapsed before the first and *only* list was made up and posted on bill-boards at nearer fifty than five hundred different places, and that list, on investigation, proved to be bogus, as neither the name nor residence of anyone on the list could be found.

They further represented that the only expense to a subscriber, when an account was sued, was ten per cent., and that not payable till the judgment was collected. When some of our members urged suit, they were politely informed they would have to put up costs.

As these fellows are going systematically from town to town throughout the State, I send this statement as a warning to my fellow practitioners that they may beware of them.

Yours very truly,

J. H. SEILER, M.D.

AKRON, OHIO,
August 25, 1896.

SOCIETY PROCEEDINGS.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twenty-second Annual Meeting, held at Philadelphia, Pa., on Wednesday, Thursday, and Friday, June 3, 4, and 5, 1896.

FIRST DAY—WEDNESDAY, JUNE 3D.

The president, F. X. DERCUM, M.D., of Philadelphia, called the meeting to order and delivered an address on

THE FUNCTIONS OF THE NEURON.

The question had arisen in his mind as to whether the neuron was not an absolutely fixed morphological element, and whether it did not possess a certain, though perhaps, limited power of movement. He found that this thought had occurred independently to three other observers, one in Germany, and two in France. Ramon Cajal, however, opposes the theory of the mobility of the neuron, and maintains that the neuroglia cells possess a great deal of mobility. He points out, for instance, that the neuroglia cells of the cortex are at times stellate, and at others much elongated. Their processes have numerous short arborescent and plumed collaterals. Two phases can be observed in them, first a state of contraction, in which the cell-body becomes augmented while the processes become shortened and the secondary branches disappear, and secondly, a state of relaxation, during which the processes of the neuroglia cells are again elongated. He further maintains that the processes of the neuroglia cells, in reality, reoresent an insulating or non-conducting material, and that during the period of relaxation they penetrate between the arborizations of the nerve-cells and their protoplasmic processes, and render difficult or impossible the passage of nerve-currents. On the other hand, when the processes of neuroglia cells are retracted, the various nerve-cell processes which they formerly separated from each other are now permitted to come into contact. It seems, therefore, that Ramon Cajal admits the very thing against which he contends.

Take the simple example of an hysterical paralysis and see how easily it may be explained. The neurons of a certain area of the cortex, for instance, retract the terminal branches of the neuraxon to such an extent that the latter are no longer in contact, or sufficiently near to the neurons in the spinal cord which supply the muscles of the paralyzed parts. When power is suddenly re-established in hysterically palsied limbs, it simply means that the terminal branches of the cortical neuraxon, previously contracted, are again extended so as to re-establish the proper relations with the spinal neurons. It would be interesting to follow out the ideas here brought forward in their application to the various phenomena presented by hysteria.

Turning to hypnotism, a ready explanation is afforded for the phenomena presented, and leaving this field entirely, we can see what an enormous value this interpretation of cortical action is for normal mental phenomena, taking for example the familiar instance of sleep.

J. J. PUTNAM, M.D., of Boston, read a paper entitled:

ACUTE NON-SUPPURATIVE HEMORRHAGIC ENCEPHALITIS.

A young boy was attacked suddenly, two weeks after having been ill with the mumps, with paralysis of motion of both eyes, and lids, deafness, coma, impairment of swallowing, right hemiparesis, and double optic neuritis. At the end of three months, however, he had recovered, except for slight double vision, and slight impairment of hearing and eyesight, and except that ever since the illness he had been subject to epileptiform attacks of short duration. These attacks were gradually becoming less frequent. Reference was also made to another case reported by the reader in 1892, where, besides other serious cerebral symptoms, including double optic neuritis, temporary loss of hearing had also occurred. The cases reported by Oppenheim were given in outline, and the interesting fact noted that his patients, like the one here referred to, were mainly children.

DR. LANDON CARTER GRAY of New York, asked if any of these cases had retraction of the neck.

DR. PUTNAM answered that he was not certain as to its presence in his own cases, but it was present in the other reported cases.

DR. GRAY thought that the best macroscopical description of hemorrhagic encephalitis had been given by Elam some years ago. All cases seen by him (Gray) had proved fatal. In many instances the diagnosis was attended with extreme difficulty. He had generally been willing to diagnose these cases as meningitis.

DR. JOSEPH COLLINS of New York, had observed a case of hemorrhagic encephalitis with autopsy, which corresponded with the description given by Oppenheim. He read the report of the autopsy which revealed old leptomeningitis, hemorrhagic encephalitis, and a pachymenin-

gitis hemorrhagica. There was no case on record in which these three conditions had been found associated.

DR. B. SACHS of New York, said that the recognition of this form of cerebral disease showed a distinct advance in neurology. He had observed four cases. Two recovered and two died. In one case there was some doubt as to whether it was meningitis or not, as there was slight retraction of the neck, but no positive coma. He looked upon it as a milder disease than basilar meningitis. In one of the patients who recovered, the cerebral symptoms appeared simultaneous with the fever. The former lasted four days, leaving the patient with slight ptosis and paresis of the external rectus.

DR. GRAY asked if fatal cases have shown more violent symptoms than those that recovered.

DR. PUTNAM replied that some of the more violent cases recovered. In general the rapid development of severe coma is considered an unfavorable sign. It is frequently quite difficult to distinguish this condition from meningitis. He believed that the severity of the symptoms depends on the amount of poison absorbed into the circulation. We do not yet know the exact significance of retraction of the neck, which is a very unreliable diagnostic sign. In one of his own cases of influenza, with symptoms of encephalitis occurring in an elderly person, the brain was found only edematous. Sometimes changes are unrecognizable with the naked eye.

WM. OSLER, M.D., of Baltimore, read a paper upon

GENERAL COMPLICATIONS OF RAYNAUD'S DISEASE.

After referring to the frequency with which Raynaud's disease is met with in forms of insanity, he said that in a few cases cerebral manifestations, due apparently to vascular changes, similar to those which develop in the peripheral parts, had been described. In the case of a man in his wards, already reported in 1891 by Dr. H. M. Thomas, in which epileptic attacks occurred in the winter months only, in connection with local asphyxia and superficial necrosis of the ears, the patient had also hemiglobinuria. In another case, a woman, aged fifty-two, during a period of six years, local syncope and asphyxia occurred at intervals in the fingers and hand of the right side, sometimes with aphasia, and on several occasions, with transient paralysis of the right arm and leg. In the final attack the patient died with gangrene of the right hand and arm. The case of Weiss is believed to be the only other instance in which aphasia complicated the disease. In a third patient "falling attacks" of an indefinite character occurred in a young girl with local asphyxia of the legs between the knee and ankle.

In answer to a question of Dr. Riggs, Dr. Osler answered that this disease was rarely fatal. This was the second fatal case with which he was familiar. The literature, however, indicates a number of fatal cases. He considered the complications as having no direct relation with the disease. The associated conditions were rarely serious.

DR. PUTNAM presented a series of photographs showing the development of cretinism at various ages.

WALTER CHANNING, M.D., of Boston, read a paper upon

TUMOR OF THALAMUS,

and presented a case. The patient was an unmarried woman of good heredity, and by occupation a school teacher. She was of an active, nervous temperament, and the subject of hay-fever and asthma until the spring of 1895, when she was under the care of a so-called "hay-fever specialist," and escaped the usual attack. Before admission to the hospital, November 29, 1895, she had been for some weeks mildly exhilarated, and extravagant in her ideas, but not enough so to interfere with her work until the 22d. The only physical symptoms she had complained of were headache and insomnia. Her disease was diagnosed by an alienist of experience as mild acute mania when she came to the hospital. Since her death, her friends have stated that she had weakness of the left arm before leaving them, but nothing was said of this in her history. She had expansive delusions and hallucinations of the taste and smell. She was unable to stand because of weakness in the left leg, and her left arm was weaker than the right, there being no power to move it above the elbow. Headache existed. There was little nausea. The pupils were equal in size and reacted to light. The eyes did not follow the finger. There was no ophthalmoscopic examination. The weakness in the left side was not so marked at the beginning as to attract special attention. It was later that its significance became apparent. Patellar reflex slightly exaggerated and alike on both sides; plantar reflex moderate; urine-color normal; reaction acid; specific gravity, 1022; urea normal; uric acid in excess; blood count, reds 4,804,000, whites 12,400. The mild maniacal excitement continued for the first week after admission. The patient was very restless in the bed, moving her head from side to side, and throwing her right arm over her head. She also often folded her arms rigidly across the chest, and clenched the fingers. After the first week she slowly sank into a stupor from which it was difficult to rouse her. The physical symptoms of central disturbance became rapidly more marked. There was entire loss of motion in the left arm, left leg, and later right leg, and extreme extension of both legs. The jaw became relaxed, interfering with respiration. The tongue fell back in the mouth. Breathing became jerky and irregular toward the end, and finally the relaxed jaw could not be replaced and death ensued. The autopsy was made by Dr. E. Wyllis Taylor of Boston, who found a boggy, cyst-like looking mass extending back an inch behind the posterior border of the optic thalamus and forward to the junction of the caudate nucleus with the thalamus, the mass apparently involving the latter in its entire extent. Microscopical examination proved the tumor to be a vascular glioma. The mental symptoms in this case seem to have been quite unlike those of the usual cases of brain tumor recorded, in which are found depression, dulness, irritability, stupor, and even pronounced dementia. Several interesting questions arise, as for instance: Which symptoms probably presented themselves first, the mental or physical? Why should there be so much mental disturbance in such a case? Was the mental trouble an accident, and independent of the tumor? If not; how can it be satisfactorily explained?

What diagnostic value do mental symptoms possess in cases of brain tumor?

DR. WHARTON SINKLER of Philadelphia, thought that the appearance of mental symptoms in thalamus tumors was of much clinical interest. In his experience, somnolence and mental symptoms were of frequent occurrence.

DR. GEORGE J. PRESTON of Baltimore, in this connection presented the specimen from a patient with hemiplegia and dementia, which showed a tumor occupying the right hemisphere, and a condition of condensing osteitis of the skull.

DR. CHAS. K. MILLS of Philadelphia, said that tumors of the brain have not only been confused with acute mania, but also with general paresis. It is sometimes very difficult to differentiate. It is not known that tumors, limited to the thalamus, produce any characteristic symptoms. They occasion mental symptoms on account of their destruction of associating cerebral fibers.

DR. SACHS had seen a case of brain tumor in a child in which mental symptoms predominated. The autopsy revealed a large tumor in the right frontal lobe. He did not feel convinced that the mental symptoms in Dr. Channing's case were attributable to the growth in the thalamus. Why might not this patient have had the mental disease independent of the tumor?

DR. THEODORE DILLER of Pittsburg, mentioned a case of tumor of the cerebellum in which the earliest symptoms were mental. The unexpected often happens in cases of brain tumor.

BURT G. WILDER, M.D., of Ithaca, N. Y., read a paper upon

THE ECTAL RELATIONS OF THE RIGHT AND LEFT PARIETAL AND PAROCCIPITAL FISSURES.

The parietal and paroccipital fissures may be either completely separated by an isthmus, or apparently continuous. When so continuous ectally, there may still be an ental and concealed vadum or shallow. Disregarding the vadum on the present occasion, the ectal relations of the two fissures may be designated as either continuity or separation. That continuity occurs more frequently on the left side has been noted by Ecker, Cunningham, and the writer. Hitherto, however, statistics have included unmated hemicerebrums as well as mates from the same individuals. The following statement is based on the cerebrums of fifty-eight adults of both sexes and various nationalities and characters. The speaker has examined forty-eight; the other ten have been accurately recorded by Bischoff, Dana, Jensen, and Mills. So far as these fifty-eight individuals are concerned, the most common combination, viz., left continuity and right separation is decidedly the rule with the moral and educated, less frequent with the ignorant and unknown, the insane and negroes, and does not occur at all in the murderers. The only instance of the reverse combination (left separation and right continuity) is an insane Swiss woman. The only two known to be left-handed represented the more frequent combination of left continuity and right separation.

JOSEPH COLLINS, M.D., of New York, read a paper upon

DOES ANTISYPHILITIC TREATMENT PREVENT THE OCCURRENCE OF THE DISEASES OF THE NERVOUS SYSTEM WHICH ARE CONSIDERED SYPHILITIC IN ORIGIN?

And pointed out that certain diseases of the nervous system occur sequentially to syphilis with such frequency that they are rightfully looked upon as syphilitic in their origin. These diseases are tabes, general paralysis, syphilitic spinal paralysis, and such exudative conditions as cerebral thrombosis. After briefly reporting the history and treatment in nearly one hundred cases observed in hospital, dispensary, and private practice, the writer concluded as follows: (1) Exudative and degenerative diseases due to syphilis, are most liable to show themselves at the end of the third and beginning of the fourth decade of life. (2) Thorough and prolonged administration of antisyphilitic remedies during the activity of the virus, does not seem to materially prolong this time limit. (3) That active and prolonged antisyphilitic treatment does seem to prevent the development of such diseases as locomotor ataxia and general paresis. This is true of degenerative diseases, though treatment may, however, have some effect in preventing the exudative diseases of the nervous system, such as syphilis of the spinal cord, disease of the blood-vessels, etc. (4) Cases of tabes and general paresis in which syphilis is confessed, and in which treatment has been most desultory and incomplete, are not more liable to the early development or to the severe manifestations of either of these two diseases than those in which the treatment has been all it should be. (5) That the administration of antisyphilitic measures in the most approved way, does not fulfil the requirements of cure, and that syphilis is often an incurable disease.

DR. OSLER said that his experience was diametrically opposed to the views of Dr. Collins. The majority of severe cases of nervous disease occurring in syphilitics were in those who had either been badly treated or not treated at all. Early, thorough, systematic, and prolonged treatment will prevent the development of degenerative disease of the nervous system in later life.

HENRY R. STEDMAN, M.D., of Boston, read a paper upon

PROGNOSIS AND DURATION OF ATTACKS OF MENTAL DISEASE.

He called attention to the fact that a general misunderstanding occurs in the community as to the curability of insanity. It is much more curable than is supposed. General paresis should not be classified among the insanities. The character of the disease has changed in the last fifty years, and our views and classification have therefore changed.

DR. GRAY said that to speak of insanity as an entity was as if one were to speak of all disease as an entity, and then go back to the old Carlyle tables of mortality for the prognosis of coryza, pneumonia, tuberculosis, typhoid fever, and cholera, while to refer to the old statistics of Pliny Earle was like referring to the hospital re-

sults of thirty or forty years ago, for guidance in the treatment of the present day. If we are to accept the statistics of results of the insane asylums, we are justified in analyzing their record, and then we are startled to find that no new type of mental disease, no original pathological observation, no new departure in treatment, and not one text-book has ever come from an American asylum, despite the millions of dollars and thousands of patients they have had at their command.

C. E. RIGGS, M.D., of St. Paul, reported a case of

PARAPLEGIA FROM HEMORRHAGE INTO THE SPINAL CORD DUE TO PERNICIOUS ANEMIA, WITH AUTOPSY.

He presented a series of spinal-cord sections.

SECOND DAY—THURSDAY, JUNE 4TH.

BURT G. WILDER, M.D., of Ithaca, presented a paper entitled

THE DORSAL SAC, THE AULIX, AND THE DIENCEPHALIC FLEXURE.

It was illustrated by specimens and photographs.

THEODORE DILLER, M.D., of Pittsburg, then read a paper upon

PROGRESSIVE MUSCULAR ATROPHY OF SUDDEN ONSET.

He related the details of a case which came under his observation three years ago, and stated that the sudden onset of palsy, followed by atrophy and the absence of sensory phenomena, led him to diagnose the case as one of poliomyelitis adultorum. The beginning of the patient's trouble was in an ophthalmoplegia. After an absence of two years the man again came under his care, when the atrophy and loss of power in the muscles had markedly increased. The biceps, triceps, scapular, and ulnar groups had become involved, and the finer movements of the fingers were lost, as was also the power of supination. At this time the patient was unable to adjust or remove his clothing unaided. There was a marked decrease in the response, both to galvanism and faradism, in the paralyzed muscles. Dr. Diller considered the case could be fairly regarded one of progressive muscular atrophy, as the progressive feature was for two years the most important feature of the case. Ophthalmoplegia, as a symptom of progressive muscular atrophy, must be rare, for but scant references are made to it in literature. Strychnin had a very marked effect in staying the progress of the disease.

WILLIAM BROWNING, M.D., of Brooklyn, described a presumably hitherto unrecognized alteration in the skin, entitled

PITTING ABOUT THE HAIR CUPS, A TROPHIC CHANGE IN THE SKIN IN CERTAIN NERVOUS DISORDERS OF CENTRAL ORIGIN.

From some seven or eight years' observation of such cases, he was able to give the limits of its occurrence. So far, it has been seen only in progressive muscular atrophy, of spinal origin, or in cases complicated with atrophy, evidently likewise due to chronic precornual disease. In other troubles attended by atrophy, as infantile palsy, neuritis, pseudo-hypertrophy, etc., it has not been found. It is hoped that it may prove a useful help in differential diagnosis, especially between the forms due to peripheral and central disease. The change consists of an areola-like faint depression, frequently oval, in the direction of the lines in the skin, though it may be irregular or circular in form, about the exit of each hair. Usually the depression is a trifle paler than the surrounding skin, resembling, but not really being, a minute scar. It is not observed in specially hairy regions like the scalp, but only over the seat of muscular atrophy, notably on the leg and thigh, though also on the upper extremities. All these patients had reached or passed middle life.

F. X. DERCUM, M.D., and WM. G. SPILLER, M.D., of Philadelphia, presented a paper on

A CASE OF SYRINGOMYELIA.

Three years after a strain of the back the patient began to suffer from pains in the legs, a band-like pain about the lower part of the chest, weakness in the lower limbs, and a spastic gait. Complete paraplegia with contractures, more marked on the right side, wasting of the lower limbs, paralysis of the bladder and rectum developed later. Cutaneous sensibility was lost in the legs, and upon the trunk as high as the nipple on the right side and a little above the umbilicus on the left. The sense of temperature was absolutely lost over the right arm, the right shoulder, and the right side of the neck, and also upon the adjacent part of the right side of the trunk above the nipple line. There was some analgesia of the right arm. The right shoulder-joint began to swell, and from rupture of the capsular ligament, cellulitis, with redness and local heat, was produced, but with little or no pain. In extension, the humerus assumed the position of a subglenoid luxation. Death was due to exhaustion.

At the autopsy the capsule of the right shoulder-joint was found much thickened and roughened on the inner surface. The head of the humerus had disappeared, the bone having been eroded to some little distance below the surgical neck. A cystic tumor was found in the axilla, containing a friable fatty material. The surface of the glenoid cavity was much eroded, roughened, and porous; it was abnormally large, and extensive bony deposit had taken place along its edges. The coracoid process exhibited a thick and firm accretion around its entire edge. Sections were made from the level of nearly every spinal root and from many spinal ganglia.

By the microscopic examination, degeneration of the crossed pyramidal tract was found as high as the substantia reticularis of the second cervical segment, and of the direct pyramidal as high as the motor decussation upon the right side, and for a short distance of the crossed pyramidal upon the left.

Degeneration of the direct cerebellar tracts and of the tracts of Gowers was traced as far as the inferior peduncles of the cerebellum. Intense pachymeningitis was noticed from the second lumbar segment to the exit of the third dorsal roots. The arthropathy of the right shoulder was not due to any special changes in the cord or spinal ganglia. The posterior roots were not affected, even where the pachymeningitis was most intense; the anterior

at one part of the dorsal cord were degenerated. In the entire cervical region, as high as the second cervical segment, the cavity was limited to the right posterior horn.

The gliosis extended from the extreme end of the conus terminalis to the second cervical segment. The microscopic examination explained satisfactorily the symptoms observed in life.

JAMES HENDRIC LLOYD, M.D., and JOSEPH SAILER, M.D., of Philadelphia, presented a paper on

RAPIDLY FATAL CEREBRITIS RESEMBLING CEREBRO-SPINAL MENINGITIS.

Fulminating cases of the infectious diseases, such as smallpox, scarlatina, measles, typhoid fever, and spotted fever, occur, in which the diagnosis is exceedingly obscure and the disease is usually quickly fatal. These cases, as a rule, have their most marked symptoms in the nervous system. There is a delirium passing into coma, with depressed cardiac and respiratory centers, high fever, and often a purpuric or hemorrhagic eruption, not always characteristic. These cases demand especially, (1) the determination of the exact effects upon the nervous system and (2) the determination of the microbe or toxic agent at work in any given case. The writers could only attempt the former study, as the paper was not intended to deal with the bacteriology of the subject.

The patient was a man, aged twenty-four years, who was taken suddenly with a chill, followed by fever and intense cephalalgia and radialgia. The patient passed rapidly into a condition of delirium merging into coma. Third-nerve paralysis supervened, and on the third day a copious purpuric eruption appeared. This eruption presented ecchymosis, and on the hands lesions like erythema nodosum. Blood and pus were found in the urine, and vomiting of blood occurred before death. The patient died on the sixth day. The autopsy revealed disseminated local lesions in the cerebrum, mid-brain, pons, and post-oblongata, some migrated leucocytes in the perivascular spaces, little involvement of the membrane, and a diffused nephritis. From extensive microscopic research the writers were able to report a disseminated local cerebritis. The infection had invaded the brain by way of the connective-tissue structures, blood-vessels, etc., and the nerve-tissues proper were invaded secondarily. From the clinical standpoint the case probably comes under the head of "spotted fever."

DR. OSLER said he should like to have heard more in regard to the condition of the kidneys in the case reported. The diagnosis of cerebritis and encephalitis can be readily made between cases of infectious fever and the former. Unless the basal meninges are involved, we cannot make a positive diagnosis of meningitis, as all these symptoms, such as retraction of the head and clonic contractions of the muscles, may be present in pneumonia, and yet nothing is found at the autopsy.

L. A. DUHRING, M.D., of Philadelphia, presented a case of

NEUROPATHIC DERMATITIS.

The patient had been under his observation for six years.

WHARTON SINKLER, M.D., of Philadelphia, read a paper by S. WEIR MITCHELL, M.D., on

THE EFFECTS OF THE FLUID EXTRACT OF ANHELONIUM LEWINII (THE MESCAL BUTTON).

It recited the personal experience of Dr. Mitchell as to the exhilarating effects, and the production of various visual hallucinations, etc., after the ingestion of a certain quantity of the drug.

WHARTON SINKLER, M.D., of Philadelphia, read a paper on

UNCERTAINTIES OF CEREBRAL LOCALIZATION.

CHARLES K. MILLS, M.D., and WM. G. SPILLER, M.D., of Philadelphia, read a paper on

A CASE OF CEREBRAL ABSCESS SITUATED AT THE POSTERIOR PART OF THE EXTERNAL CAPSULE.

The patient had never had earache, but had suffered during the summer of 1895 from severe headache. On December 20, 1895, he became unconscious and had three general convulsions which resembled those of epilepsy. It was noticed that he was partially paralyzed on the right side and that he could not talk properly. His condition later improved very much. On January 29, 1896, he had another attack of partial unconsciousness, without convulsions, but with aphasia and decided paralysis. On admission to the hospital he was in a condition of stupor; he did not speak when addressed, and had almost total right-sided paralysis, incontinence of urine and feces, and entire loss of pain- and touch-sense over the paralyzed side. He was found to have right homonymous hemianopsia and double papillitis, most marked in the left eye. Death occurred February 26, 1896. There was no evidence at any time of middle-ear disease. At the autopsy an abscess was found in the left hemisphere, just above the level of the callosum. Both tympanic membranes were normal. Microscopic examination of the pus from the cerebral abscess revealed only the ordinary *Staphylococcus pyogenes aureus*.

The occurrence of epileptiform convulsions at the time of the first attack of unconsciousness, probably due to irritation of the motor fibers within the internal capsule, is worthy of note as an instance of the difficulty in diagnosticating cortical lesions. It is not known in what portion of the body these convulsions began. The diagnosis was made of some morbid process located at the posterior part of the internal capsule, involving the optic radiations and causing pressure. The abscess occupied the posterior part of the external capsule, a portion of the lenticular nucleus, and extended downward into the subthalamic region, but to all appearances had not cut the fibers of the optic radiations nor those of the internal capsule. The loss of function in these tracts was probably due to pressure. The white matter of the first temporal gyrus was almost entirely destroyed, and fibers from the upper anterior part of the second temporal were also cut. As the cavity was very near the periphery of the first temporal convolution, it would not have been difficult for the surgeon to have emptied it. Hearing was probably not seriously affected, although word-deafness appeared to be

present. In view of the frequency of cerebral abscess after suppurative processes in the lungs, it may be added that merely spots of catarrhal pneumonia were found in both lungs at the autopsy. No degeneration was noticed anywhere in the motor tract. At all parts a good half-inch of sound tissue existed at the posterior part of the internal capsule in the area corresponding to the optic radiations and the tract of Turck. It has been claimed by Dejerine that fibers arise in the temporal lobe (especially in the second and third convolutions) pass inward below the putamen, join the posterior part of the internal capsule in the subthalamic region and then form approximately the external fifth of the cerebral peduncle. No fibers from the occipital lobe are found in this lateral bundle of the crus. Dejerine has found this tract of Turck degenerated in six cases of lesions involving the middle and inferior part of the temporal lobe. In the case reported the fibers from the first temporal gyrus were almost entirely destroyed as well as those from the upper anterior part of the second temporal convolution, and as no degeneration was found within the lateral bundle of the peduncle by the method of Marchi sixty-eight days after the first attack and twenty-eight days after the second, certainly a period sufficiently long for this method. The authors consider that the case demonstrates the fact that no fibers from the first temporal and the upper anterior part of the second temporal gyrus, including a portion of the upper middle of this gyrus, enter the fasciculus of Turck. This does not render impossible or improbable the origin of such fibers in the lower anterior and the whole of the posterior part of the second temporal and in the whole of the third temporal gyrus. The fibers which enter the first temporal gyrus are probably connected with the sense of hearing, and, being sensory, probably do not degenerate downward, which accounts for the absence of secondary degeneration in the peduncle.

B. SACHS, M.D., and A. G. GERSTER, M.D., of New York, read a paper on

THE SURGICAL TREATMENT OF FOCAL EPILEPSY; A CRITICAL ANALYSIS OF THE RESULT IN NINETEEN CASES.

The authors' views and experiences are summed up in the following conclusions: (1) That surgical interference is advisable in those cases of partial epilepsy in which not more than one, or at the utmost, two years have elapsed since the traumatic injury or beginning of the disease which has given rise to the convulsive seizures. (2) In case of depression or other injury of the skull, surgical interference is warranted, even though a number of years have elapsed. But the prospect of recovery is brighter the shorter the period of time since the injury. (3) Simple trephining may prove sufficient for a number of cases, and particularly in those cases in which there is an injury to the skull or in which a cystic condition is the main cause of the epilepsy. (4) Excision of cortical tissue is advisable if epilepsy has lasted but a short time and if the symptoms point to a strictly circumscribed focus of disease. (5) Since such cortical lesions are often of a microscopical character, excision should be practised even if the tissue appears to be perfectly normal at the time of operation, but the greatest care should be exercised in order to make sure that the proper area is removed. (6) Surgical interference for the cure of epilepsy associated with infantile cerebral palsies may be attempted, particularly if too long an interval has not elapsed since the beginning of the palsy. (7) In cases of epilepsy of long standing, in which there is, in all probability, a widespread degeneration of the associated fibers, every surgical procedure is absolutely useless.

JOSEPH COLLINS, M.D., and A. WIENER, M.D., of New York, presented

A CONTRIBUTION TO THE PATHOLOGY OF EPILEPSY AND A RÉSUMÉ OF THE UTILITY OF OPERATION IN EPILEPSY.

This was a report of two cases in which a portion of the cortex was excised. The first case was that of a young man, twenty years of age, with the usual symptoms of focal epilepsy, the patient having had but three attacks. The cortical area for the right hand was cut out. Microscopical examination of the tissue showed chronic meningo-encephalitis, obliterative changes in the blood-vessels, changes in the ganglion cells of a degenerative character, and the formation of neuroglia tissue in the softened area. The patient was operated upon a year ago, and has since been free from epileptic attacks. The second case was that of a married woman, thirty years of age, who had epilepsy for six years of a focal character at first, which later became general. A similar operation was performed, and the cortex showed unmistakable pathological changes.

W. W. KEENE, M.D., of Philadelphia, and H. M. THOMAS, M.D., of Baltimore, reported a

CASE OF A LARGE TUMOR REMOVED FROM THE BRAIN WITH WIDE OPENING OF THE LATERAL VENTRICLE.

The patient, a young man of nineteen, with an excellent family and personal history, and no history of accident, in December, 1895, had an attack of intense headache and vomiting, but without optic neuritis. The latter symptom followed in the middle of January, with later blindness in right eye, slight vision remaining in the left; slight protrusion of left eyeball, pupils equal and normal, smell, hearing and taste unaffected. Paresis of the lower right face, sensation and the muscles of mastication unaffected, no muscular weakness in either the arms or legs, but there was a good deal of muscular restlessness of the right hand, persisting even during sleep. Reflexes present. Mental condition poor. He was dull and apathetic and sometimes slightly wandering mentally. After the early headache and vomiting neither of these was a marked feature. There was slight aphasia. Drs. Osler and Starr saw the patient with Dr. Thomas, and the conclusion was reached that it was a tumor in the left frontal lobe, most likely at the base of the second frontal convolution and probably subcortical. On May 10 Dr. Keene operated. The tumor presented through a rupture of the cortex at the base of the second frontal convolution as had been diagnosticated. The tumor was easily scooped out by the fingers. The lateral ventricle

was then seen to be widely open. After the operation there was no increase of the paralysis. In two weeks the patient had entirely recovered. The tumor was 7.5 cm. long, 5.5 cm. broad, and 4 cm. deep, and weighed two and a half ounces. It was a hard non-infiltrating sarcoma.

DR. A. G. GERSTER, of New York, confined his remarks principally to craniotomy in reference to cases of epilepsy. He spoke of the dangers in the use of the trephine and chisel, and recommended the bone-flap operation as introduced by Krause and performed by aid of the chisel and rongeur. He considered all of these methods unsatisfactory and too slow. He exhibited the electrical saw by Krause.

The greatest danger in cranial operations is due to hemorrhage on account of the prolonged time of the operation. Therefore, any apparatus is desirable that will enable the surgeon to work with rapidity and safety. He presented an American apparatus based on the principles of the dental drill, and said he had used the instrument with satisfaction in four cases.

DR. M. A. STARR had seen twenty-four cases operated upon but none were cured. He has never recommended, and will not recommend, operation in idiopathic epilepsy. He has always had the advantage of a skilful operator. These operations should only be done by surgeons who have special experience in this line of surgery, and not by the general surgeon. The exsection of cysts is very unsatisfactory as death on the table has often followed. He had seen cases operated on very early in infantile epilepsy, due to meningeal hemorrhage, without favorable result. When brain tissue, either scar tissue, or normal tissue, has been excised, the attacks have also recurred. Of eleven cases of brain abscess operated upon, three recovered. All of these were seen at the various hospitals, and were usually subsequent to ear disease. He could not agree with Macewen's view as to the simplicity of diagnosis of cerebral abscess. He thought the day of trephining was over. The last operation witnessed was done in 14½ minutes by chisels and gouges.

DR. W. W. KEENE spoke at length on the report of the case presented conjointly by him and Dr. Thomas, and considered the prognosis favorable. The removal of large tumors seems to be less dangerous to life than small ones, as in the search for the latter we are likely to damage the brain extensively. It is only within the last ten years that cranial surgery really began. His experience had been moderately large. He agreed with Dr. Starr as he (Dr. Keene) had not seen a single case of epilepsy cured by operation. He would be unwilling to accept even two years, but thought three years preferable as the limit for disappearance of attacks after operation. He had, however, seen considerable amelioration and, therefore, thought it worth while to operate in certain cases. He would not operate in cases of general idiopathic epilepsy. The sooner the operation is done after the injury or the beginning of epilepsy the more favorable the prognosis. After epilepsy had existed five or six years, he would hesitate in operating. He concluded that we must have twenty years of experience in cerebral surgery before this matter can be satisfactorily settled.

DR. J. H. LLOYD presented a patient with right hemiplegia and contracture, unilateral sweating and flushing of the face, and dilation of the pupil, and looked upon the latter symptoms as due to an irritative lesion of the thalamus.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL, DEPARTMENT, U. S. ARMY, FROM AUGUST 25, 1896, TO AUGUST 31, 1896.

Major Henry S. Turrill, Surgeon, upon being relieved from duty at Fort Riley, Kan., is ordered to Willets Point, N. Y., for duty, relieving Major Egon A. Koerper, Surgeon.

Major Koerper, upon being thus relieved, is ordered to Fort Crook, Neb., for duty.

First Lieutenant Frederick P. Reynolds, Assistant Surgeon, is relieved from duty at Fort Clark, Tex., and ordered to Fort McIntosh, Tex., for duty, relieving First Lieutenant Robert S. Woodson, Assistant Surgeon.

Lieutenant Woodson, on being thus relieved, is ordered to Jackson Barracks, La., for duty at that station, relieving Captain Junius L. Powell, Assistant Surgeon.

Captain Powell, on being thus relieved, will report to the president of the examining board appointed to meet at the office of the Surgeon General of the Army, for examination for promotion, and upon conclusion of examination, is ordered to Fort Riley, Kan., for duty, relieving Major Henry S. Turrill, Surgeon.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE SIXTEEN DAYS ENDED AUGUST 31, 1896.

BAILHACHE, P. H., Surgeon. Detailed to represent Service at meeting of American Public Health Association, August 24, 1896.

PURVIANCE, GEORGE, Surgeon. Relieved from duty at Philadelphia, Pa., and directed to proceed to St. Louis, Mo., and assume command of Service; August 25, 1896.

HAMILTON, J. B., Surgeon. When relieved from duty at Chicago, Ill., to proceed to San Francisco, Cal., and assume command of Service; August 25. 1896.

CASSAWAY, J. M., Surgeon. Granted leave of absence for thirty days from October 1, 1896; August 24, 1896.

GODFREY, JOHN, Surgeon. When relieved from duty at San Francisco, Cal., to proceed to Chicago, Ill., and assume command of Service; August 25, 1896.

WHEELER, W. A., Surgeon. When relieved from duty at Ellis Island, N. Y., to proceed to Cincinnati, Ohio, and assume command of Service; August 25, 1896.

BANKS, C. E., Surgeon. To proceed from Washington, D. C., to Boston, Mass., for temporary duty; August 21, 1896.

CARMICHAEL, D. A., Passed Assistant Surgeon. Granted leave of absence for thirty days from September 5, 1896; August 17, 1896.

WASDIN, EUGENE, Passed Assistant Surgeon. Granted leave of absence for five days; August 25, 1896.

BROOKS, S. D., Passed Assistant Surgeon. Directed to rejoin station at St. Louis, Mo., and when relieved from duty at that place to proceed to Port Townsend, Wash., and assume command of service; August 25, 1896.

WHITE, J. H., Passed Assistant Surgeon. Relieved from special duty at Key West, Fla , and directed to rejoin station at New York; August 24, 1896. Detailed for duty in connection with Immigration Service at Ellis Island, N. Y.; August 25, 1896.

CARRINGTON, P. M., Passed Assistant Surgeon. To proceed to Chicago, Ill., and assume temporary command of Service; August 25, 1896.

KINYOUN, J. J., Passed Assistant Surgeon. Detailed to represent Service at meeting of American Public Health Association; August 24, 1896.

THE MEDICAL NEWS.

VOL. LXIX. NEW YORK, SATURDAY, SEPTEMBER 26, 1896. No. 13.

ORIGINAL ARTICLES.

THE DISEASES OF THE SKIN, OBSERVED IN A GENERAL PRACTICE OF TWENTY-FIVE YEARS, AND THEIR TREATMENT.[1]

BY CHARLES E. LOCKWOOD, M.D.,
OF NEW YORK.

ECZEMA is by far the most common of all diseases of the skin encountered in this country, and the statistics of the American Dermatological Association for five years ending in 1884, according to Van Harlingen, showed that out of 58,617 cases of skin disease occurring in all parts of the United States and Canada, 18,525, or nearly thirty-two per cent., were cases of eczema.

Eczema may be acute, subacute, or chronic, according to the rapidity of its progress and accompanying constitutional disturbance. I have met with acute eczema, accompanied with fever and constitutional disturbance, only once or twice.

The following case of infantile eczema was observed by me in March, 1886:

M., age three months, nourished on the breast by a wet-nurse, developed a general subacute eczema of the face, body, arms, and legs, probably due to indigestion. The following treatment was employed March 10, 1886: General baths were interdicted; skin was sponged with bay rum one part, water four parts; no flannel underwear allowed next to the skin. To the eruption an application of ol. rusci ʒ j, cold cream ℥ jss, was made twice a day with tip of finger, and on raw places, after applying the ointment, a solution of flexible collodion ℥ j in sulphuric ether ℥ ss was applied. Internally, a pinch of bicarbonate of soda was given three times a day, and every five days a powder of one grain of calomel and one grain of sodæ bicarb. March 20th, condition of face and body was much improved. I ordered a half-teaspoonful of lime-water, diluted with water, three times a day, and locally, the following powder to be dusted on the eruption, which was not so red or scaly:

℞ Pulv. Zinc Oxid. . . . . ℥ ss
Pulv. Amyli . . . . . ℥ j
Pulv. Camphor . . . . . ʒ ss

For itching paint on the skin:

℞ Tr. Camphor
Tr. Benzoin Co. aa . . . ℥ j

March 23d, face and head were nearly clear of the eruption, although some remained on the arms and legs. Child nursed regularly every four hours. The same treatment was continued, and the skin was sponged with Listerine and water, and a mixture of rhubarb and soda given two or three times a day.

April 22, 1886, the eruption had entirely disappeared.

This case illustrates well the marked benefit of soothing and non-irritating remedies when locally applied to the tender and sensitive skin of an infant.

In eczema of the hands and fingers, I have found rubber finger-covers and gloves useful as a protective applied over proper local dressings. The two following cases will illustrate this class:

T. C., laborer, age thirty-four years, consulted me in March, 1893, suffering from eczema of the back of the right hand, which extended from the knuckles to the wrist and over the back of the hand from one side to the other. The whole surface was red and swollen and raw-looking, and gave exit to a most offensive discharge. The patient was anemic in appearance and suffering from constipation. His mother had been treated by me for eczema of the leg, some years before. Considering this to be a case of chronic eczema, I prescribed Fowler's solution of arsenic, beginning with two-drop doses three times a day after meals; pil. Blaud, five grains after each meal; one-fortieth of a grain of podophyllin three times a day, and, as a local application, ungt. hydrarg. ammoniat. ℥ j, tincture benzoin co. five minims. The dose of Fowler's solution was gradually increased until, on April 11, 1893, he was taking seven drops, and the raw surface on the back of the hand was almost entirely healed over and covered with healthy skin. I next prescribed pil. podophyllum (Squibb), one every third night, until five should be taken, and as a local stimulant, ol. cadini ʒ j, ungt. hydrarg. ammoniat ʒ vij.

June 2, 1893, the patient had increased the dose of Fowler's solution to nine drops after meals. He suffered from looseness of the bowels whenever the dose of arsenic was increased, but this passed away in twenty-four hours when the dose was decreased. Continuing the tonic treatment, I prescribed Flint's tablets, saline and ferric tonic, two after meals.

June 13, 1893, he was suffering from diarrhea, and he had decreased the dose of arsenic from ten drops to six drops three times a day. The hand was almost entirely well, there being only a little redness on the wrist. I ordered the arsenic stopped and prescribed succus alterans, one teaspoonful three times a day. I did not see the

[1] Read at the twelfth annual meeting of the Fifth District Branch of the New York State Medical Association, held in Brooklyn on May 26, 1896.

patient again, but one year afterward his mother called on me and informed me that he recovered completely and had had no further recurrence of the trouble.

This case illustrates the efficacy of arsenic in certain cases of eczema, combined with iron—liver stimulation—and that empirical class of remedies called alteratives, among which I include succus alterans, a combination of stillingia, sarsaparilla, phytolacca, lappa, and xanthoxylum.

H. R., female, aged forty-seven, born in Ireland, single, occupation a cook, consulted me in October, 1889, for eczema of three fingers of the right hand, with which she had suffered for four months. Her family history was good, and she had always enjoyed good health. I was unable to obtain any evidence of a rheumatic or strumous diathesis, or liver, stomach, kidney, or uterine trouble. She was somewhat anemic, and I prescribed as a general tonic:

℞ Tr. Ferri Muriat . . . ʒ ij
Liq. Potass. Arsenit . . min. xlviii
Aquæ . . . . . ℥ iij
One teaspoonful in one-third tumbler of water after meals.

and as a local application:

℞ Hydrarg. Chlorid Metis . . . grs. x
Ungt. Tinc. Oxid. } aa . . . ℥ ss
Vaselin }
Apply to the fingers on soft linen and cover with a a rubber glove or rubber finger-covers.

October 31, 1889, the fingers were better; dry, red, and scaly. The amount of calomel in the ointment was increased to twenty grains, and the dose of Fowler's solution of arsenict of our drops, after which the affection was cured.

Eczema aurium, or eczema of the external auditory canal, I have met with only twice; and as this form of the disease sometimes presents some difficulty in the way of diagnosis and treatment, I shall present the history of one case. In both of these cases there was a family history of gout and rheumatism, and one suffered from gouty inflammation of the feet and toes.

W. R., white, born in New York, age thirty-two, weight 150 pounds, occupation mechanical engineer, consulted me in November, 1895, and gave the following history: Three or four years ago, while sitting in the car near an open window, he noticed an itching and ringing in the right ear. He visited an ear dispensary and was told he had inflammation of the ear, and was given powders. He then consulted a physician, who told him to wash the ear with warm water. When I saw him, the external auditory meati and canals of both ears were almost occluded by swollen tissues and coated with dry and moist scales, and he complained of ringing in the ears and a very disagreeable feeling in the external auditory canals. In order to clean out the canals so as to be able to make a positive diagnosis, I first dropped in both ears "Ozonol," a solution of ozone in oil, to soften and loosen the scales, and then, with a dropper, "Pyrozone," a three per cent. solution of dioxid of hydrogen, after which I syringed the ears with warm water, to which were added bicarbonate of soda and glycerin. After cleansing the ears as thoroughly as possible, I was still unable to see the drum, and gave him the following prescription to drop in the ears:

℞ Acid Boric . . . . . grs. x
Cocain Muriat . . . . . grs. iv
Alcohol }
Glycerin } aa . . . . ʒ jss
Rose-water }
Sig.—Drop five drops in the ears twice daily.

November 13, 1895, patient's condition was so much improved that I was able to see both drums. I painted over the surface affected a solution of nitrate of silver, two grains to the ounce, and closed the canals with a small piece of cotton, loosely inserted, as a matter of protection from the air. I prescribed ol. rusci, eight minims, to one ounce of vaselin, to be painted in the ears daily after syringing them with a solution of boric acid, two teaspoonfuls to a tumbler of warm water. In view of the rheumatic history in the family, I ordered five grains of salicylate of soda to be taken three times a day, two hours after meals, Poland water, as a drink, to be used freely, and the taking of red meats only once during the day, with the result that recovery was thereafter uninterrupted.

I have met with one case of eczema capitis, the history of which I gave in a paper read before the New York State Medical Society in February, 1895. In this instance the eruption had existed, off and on, for four years, and the patient gave a history of having suffered from rheumatism during the same period, the rheumatism disappearing after the breaking out of the eruption. The treatment, which consisted in the administration of salicylate of soda in ten-grain doses three times a day, with half a teaspoonful of bicarbonate of soda in carbonic acid water, twice a day, and the application of black wash and a stimulating ointment locally, and subsequently the administration of Fowler's Solution of arsenic in two-drop doses with wine of iron, and one-fortieth of a grain of podophyllin three times a day for four or five days at a time, resulted in a complete cure.

In the following case of chronic eczema of the forearms and legs, the patient came under my care November 12, 1890, and was discharged cured May 12, 1891:

Miss K., age thirty-one, had always enjoyed good health, with the exception that for three years she had had an eczematous eruption on the palmar aspect of the right forearm. It disap-

peared one summer and came back in the fall. A general examination showed an anemic murmur over the large vessels in the neck, and she complained of having suffered recently from neuralgia of the face and flatulence after eating. She was ordered to wash the arm with tar soap nightly and to take Fowler's Solution of arsenic in two-drop doses after meals; afterward the Fowler's Solution was given up to eight-drop doses after meals, with the result that she complained of sickness at the stomach, and the eruption was no better. The eruption was then painted with tincture of iodin to remove the epidermis, and the following ointment applied locally: Ungt. hydrarg. ammoniat. ʒ j, ungt. zinc oxid ℥ j. Iron in the form of Blaud's pills, five grains each, was prescribed three times a day after meals, to be gradually increased to three pills after meals. After two months' treatment the eruption was hardly to be seen. Adding a local application of green soap and stimulating ointments for a month, on April 13, 1891, eczematous spots appeared on the right and left forearms and right leg, and the anemic murmur in the neck had disappeared. I prescribed succus alterans, one teaspoonful after meals, and directed her to wash the eruption every night with ichthyol soap and apply an ointment of ammoniate of mercury. April 23, 1891, the eruption was better, and the dose of succus alterans was increased to two teaspoonfuls after meals. The local treatment as before. May 12, 1891, the eruption was entirely gone. The patient complained of pain during the evening after supper, at times, and says she wakes up in the night with pain and vomiting, for which I prescribed a powder of bismuth subnitrate, sodæ bicarb., pepsin, each ʒ ij, pulv. zingiber ʒ j, a half teaspoonful in water after meals, with good effect.

This case illustrates the importance of our appreciation of gastric disorder and anemia as factors in the production of eczema, and the inefficacy of arsenic in such cases, except in very small doses combined with iron.

In varicose eczema I have always secured good results by combining careful attention to the local support of the dilated veins, with proper general and local treatment. Eczema of the face, with abrasion of the mucous membrane of the mouth, I have met with in a patient who gave a history of syphilis contracted twenty-five years before, and a gouty family diathesis, which yielded to the local application of an ointment of calomel, ʒ j to the ounce, and the internal administration of the mixed treatment, combined with remedies suited to the gouty diathesis.

Eczema in the neighborhood of the lips, with cracks and fissures of the skin and mucous membrane at the corners of the mouth, I have met with once in a strumous subject. These cases are peculiarly rebellious to treatment, especially in cold weather. The treatment adopted was the internal administration of cod-liver oil and the syrup of the iodid of iron, and the local application of the following ointment: ol. rusci, eight minims; vaselin, one ounce, resulting in recovery. In another case, if I should find the fissures at the corners of the mouth slow in healing, I should try the application of

℞ Flexible Collodion . . . . ℥ j
Sulphuric Ether . . . . ℥ ss

painted over the fissures after the application of the ointment.

As soothing applications in the acute stage of eczema, I can recommend the calamin lotion:

℞ Zinc Oxid . . . . . ℥ ss
Pulv. Calamin Præp. . . . ʒ iv
Glycerin . . . . . ℥ j
Liq. Calcis . . . . . ℥ vij
Sig.—Mop on skin or bind on with cheese-cloth.

or,

℞ Tr. Opii Liq. Plumbi Subacetat . ʒ ijss
Aquæ Rosæ . . . . . ℥ iv

As a soothing powder,

℞ Pulv. Zinc Oxid, Pulv. Amyli, Pulv. Lycopodium } aa . . . ℥ ½

As an astringent ointment,

℞ Acid Tannic . . . . . grs. v
Bismuth Subnitrat . . . . ʒ ss
Ungt. Aquæ Rosæ . . . ℥ j

As a stimulating ointment in the stage of hyperemia with infiltration,

℞ Picis Liquid . . . . . ʒ ss
Zinc Oxid. . . . . ʒ iij
Ungt. Aquæ Rosæ . . . . ℥ ij

Ichthyol has been highly recommended as a local application in acute and chronic eczema, but I have had no experience with it.

As a blood depurative, I can highly recommend a preparation suggested by Dr. H. G. Piffard, having relieved one case of eczema of the legs almost immediately by its use. The formula is as follows:

℞ Herb Violæ Tricoloris . . . ℥ j
Fol. Sennæ . . . . . ℥ ss
Aquæ Bullientis . . . . O ij

Let it stand until cool and then strain. Of this, the average dose is a tumblerful once or twice a day. It should be given, however, in quantity sufficient to produce four or five evacuations daily for two or three days, after which the dose may be diminished. The effects of active purgation with this infusion is in some cases of eczema, as Dr. Piffard says, very surprising.

Erythema is found in two varieties: *Local or Idiopathic* and *Symptomatic*, including the erythemata which occur in parts of other and general diseases.

In the former the disease is merely hyperemia, without much, if any, appreciable effusion into the cutis and cellular tissue; in the other there is more escape of serosity from the vessels. As an illustration of the second variety, I give the following history:

On February 17, 1896, I was asked to see a young girl, aged fifteen years, who had been suffering for two or three days from an alveolar abscess connected with the roots of the first lower molar tooth on the right side. The tooth had been removed, but she was still suffering considerable pain, due to the irritation and pressure of inflammatory products upon the sensitive ends of the branches of the fifth nerve. Her temperature, taken under the tongue, was 100⅘°; pulse 84, and she suffered from frequent urination, passing her urine every hour. Over her face, hands, arms, and about her waist, there was a marked erythema, which had come out around the glandular orifices and disappeared on pressure. This eruption caused considerable anxiety in the family, but as my diagnosis was erythema, I was able to reassure them. For the cleansing of the foul cavity from which the tooth had been removed, I prescribed a mouth-wash of carbolic acid, one dram to the pint of water, with the addition of a little glycerin, the application of a two-per-cent. solution of cocain on cotton (being careful to place only about four or five drops on the cotton, containing about one-tenth of a grain of cocain, and directing her not to swallow her saliva while cocain was in her mouth) to relieve pain, and the use of fifteen grains of citrate of potash and five minims of fluid extract of hyoscyamin dissolved in a teaspoonful of water and flavored with essence of lemon to relieve the frequency of urination. These measures relieved her distressing symptoms, but she subsequently was attacked with violent pain in the stomach, and nausea, which I relieved by a hypodermic injection of one-eighth of a grain of morphin. The erythema appeared February 17th and disappeared February 19th, with improvement of the other conditions.

Acne is one of the commonest skin diseases, according to the statistics of the American Dermatological Association. Its causes, active and predisposing, are local irritation, blood-states, reflected mischief, and puberty, at which time the circulation around the sebaceous glands incident to the growth of hair is particularly active and therefore particularly liable to derangement in anemia, scrofula, dyspepsia, constipation, uterine disease in females, and affections of the genital organs in the male.

Acne punctata, or comedo, I have found very rebellious to treatment, yet in some cases I have seen marked improvement follow the use of local remedies to promote removal of the sebaceous plugs and hyperemia, followed by lotions or ointments calculated to restore tone to the sluggish circulation, with internal remedies to remove dyspepsia, constipation, and liver inaction, improve the general tone and correct depraved conditions of the blood, as cod-liver oil and iodid of iron in scrofula, preparations of iron in anemia, and nerve-tonics, such as preparations of the hypophosphites with small doses of strychnia in irritable conditions of the nervous system due to disturbance of the balance of nutrition. The condition of the genito-urinary organs should be inquired into. The local applications which I have found most generally useful have been hot water and soap, followed by preparations of corrosive sublimate or sulphur in the form of lotions or ointments, as in the following:

℞ Ammoniæ Hydrochlo. . . . grs. xv
Hydrarg. Chlorid Corrosive . . grs. vj
Cochinillini . . . . . gr. ss
Aquæ Rosæ . . . . . ℥ iij
Sig.—Rub firmly on the skin night and morning.

℞ Hydrarg. Chlorid Corrosiv . . gr. jss
Pulv. Camphor . . . . . grs. x
Ungt. Aquæ Rosæ . . . ℥ j
Sig.—Rub on the skin night and morning.

℞ Sulphur Præcipitat. . . . ℥ i
Spts. Vini Recti . . . . ℥ j
Sig.—Rub on the skin with a piece of flannel night and morning.

Mrs. H. M., age twenty-seven years, married three years, pregnant three months, consulted me February 10, 1896, suffering from comedo or acne punctata affecting the sebaceous glands of the forehead, temples, and hairy scalp, accompanied with symptoms of indigestion and constipation and strumous enlargement of the glands of the neck. The following treatment was prescribed for the indigestion:

℞ Ess. Pepsin . . . . . ℥ iv
Acid Nitro Muriatic Dilut. }
Tr. Nucis Vom. } aa . . ℥ j
Bismuth Subnitrat. }
Sig.—Two teaspoonfuls in a quarter of a tumbler of water, before meals.

For the constipation, one tablet containing five minims of the fluid extract of cascara sagrada was given two or three times a day. A piece of gauze dipped in hot water and with some tincture of green soap was rubbed over the affected parts night and morning. Afterward the following lotion was applied to the forehead and temples:

℞ Sulphur Præcipitat. . . . grs. xlv
Boric Acid . . . . . grs. xv
Ether }
Cologne-water } aa . . . ℥ ij
Alcohol . . . . . ℥ iij

To the scalp I recommend the application of a five-per-cent. solution of resorcin in equal parts of alcohol and water, with one dram of glycerin

February 17, 1896, the face was much improved,

and the scalp still scaly. I prescribed cod-liver oil and Blancard's pills of iodid of iron.

March 7, 1896, the patient recovered.

Acne simplex I have met with very frequently in practice in neurotic subjects suffering from general loss of nerve-tone, indigestion, anemia, malnutrition, or reflex irritation from diseased or abnormal conditions of the sexual organs. I shall give the history of one case, in which three different diseases of the skin were illustrated:

C. P., white, age thirty-six years, lawyer, weight 160 pounds, neurotic temperament, consulted me in March, 1889, and gave the following history: Has never had any severe illness, was perfectly well up to three or four years ago, since which time he has suffered from a thick feeling, as he expresses it, in the head, and a full feeling in the stomach. He noticed his eyesight failing in 1888, and complains of defective eyesight at the present time.

I asked Dr. Mittendorf to examine his eyes, and he reported as follows:

His case is one of the greatest interest to me; it is one of retinal and choroidal congestion. I do not think it very serious at present, but another attack of this kind may lead to exudation into the vitreous humor, and detachment of the retina. If you see him, will you please look after his digestion?

An examination showed an eruption of acne on the chest and back, due probably to indigestion and malnutrition, depraved nerve-tone and reflex irritation. A careful examination of the urine showed crystals of oxalate of lime; no albumin; no sugar. He was ordered to take a powder of bismuth, soda, pepsin, and ginger after meals, and, as a liver-stimulant, the following every night for twenty days:

℞ Euonymin, Irisin, Leptandrin aa . . . . . gr. j
Fl. Ext. Ipecac . . . . . ¼
M.—Ft. one pill.

March 25, 1889, his condition was the same. I prescribed ten drops of nitro-muriatic acid dilute in one tablespoonful infusion gentian co., after meals.

April 1, 1889: No oxalate of lime was found in the urine. He had flashes of light before the eyes when he got up in the morning or went upstairs quickly. There were no new acne spots; very little indigestion. For constipation, I ordered Buckthorn cordial, a teaspoonful to a tablespoonful at bedtime, and after meals a preparation of cod-liver oil, pepsin, and quinin.

April 8, 1889, the acne was better, but there appeared an eruption of herpetic vesicles on both buttocks, for which I prescribed the local application of the following lotion:

℞ Listerine, Aromat. aa . . . . . ℥ ijss
Aquæ . . . . . ℥ j
M.

April 15, 1889, the herpes was better, the bowels were regular, and there was very little indigestion. To continue the building-up treatment, I ordered him to take one tablespoonful of Moller's cod-liver oil after meals with ten drops of Thompson's solution of phosphorus.

The condition of this patient was improving until, on June 10, 1889, he appeared with acne on the back and chest again, having eaten a supper of lobster and crabs. This disappeared under proper treatment directed to stomach, liver, and general nutrition, and I saw no more of him until February 26, 1892, when he appeared, suffering from indigestion, fulness of head after eating, buzzing in the ears and flashes of light before the eyes, and a red, itchy, burning, vesicular eruption on the forearms, shins, and toes, which I recognized as eczema. It yielded to treatment based on the principles of stimulation of the liver, correction of digestion, and administration of tonics, with local applications, first soothing and then stimulating, as adapted to the stages of the trouble.

In acute urticaria, it is necessary, before prescribing treatment, to decide whether the trouble is the result of local irritation, disordered stomach, or reflex irritation from some other organ. If due to some dietetic error or stomach disorder, I have always been able to secure a favorable result by the administration of four grains of calomel, followed in six hours by a bottle of citrate of magnesia, combined with the soothing effects of a warm bath containing from three to six ounces of bicarbonate of soda to thirty gallons of water, and, as an antipruritic, sponging the skin with vinegar and water dilute acetic acid, or the following:

℞ Acid Carbolic . . . . . ℥ iij
Glycerin . . . . . ℥ j
Aquæ . . . . . O j
M. Sig.—Apply to the skin with a soft sponge.

Colchicum with salines have been recommended in gouty cases; acetate of potash and tincture of digitalis when fever runs high, and emetics in cases due to dietetic errors.

In cases of chronic urticaria the condition of the mind and the nervous system in general, the functions of stomach, intestines, liver, and kidneys, diet and manner of eating, and blood states demand the closest attention.

In October, 1895, I was consulted by a lady about forty years of age, who complained of an eruption of red blotches, which began in July, 1895. It came and went, as she expressed it, and was attended with intolerable burning, tingling, and itching. She seemed to be in perfect health, but gave a history of having lived in Germany near Hamburg during the preceding summer, and of having partaken freely of the peculiarly Ger-

man articles of food. A careful general examination showed some mental depression, and I was able to detect an anemic murmur over the base of the heart. She gave a family history of a gouty diathesis, her father, brother, and six sisters all having suffered from that trouble. After the removal of all local sources of irritation, such as flannel underwear, the avoidance of cold draughts, and the regulation of the diet, the local use of antipruritics, such as carbolic acid and vinegar and water, she was put on two-teaspoonful doses of Gude's syrup peptomanganate of iron three times a day, after meals, which was continued for about two months, with the result of, at first, slow improvement, and finally perfect cure.

In another case of this character, with well-marked symptoms of stomach disorder, I was compelled to insist on an exclusive diet of peptonized milk in connection with remedies indicated for anemia, which was evident.

Pityriasis versicolor, or chromophytosis, produced by the growth of the fungus *Microsporon furfur* among the horny cells of the epidermis and characterized by the appearance of yellowish-brown spots upon the chest and abdomen, I have met with quite frequently. For the destruction of the parasite I have recommended the washing of the parts with yellow soap or tincture of green soap and the application of a lotion composed of four or six drams of hyposulphite of soda and six ounces of water, or the application of tincture of iodin, or washing the spots with undiluted sulphurous acid, continuing the use of the parasiticide for a few days after the disappearance of the disease. Frequent changing and disinfection of the clothes worn next to the skin, and tonics, with nourishing diet, are necessary, as the affection usually occurs in debilitated subjects.

Pediculosis pubis I have always treated successfully by lotions of corrosive sublimate. In the male I have used a solution of two grains of corrosive sublimate to one ounce of cologne-water, or one per cent. solution (about eight grains to the pint) in equal parts of alcohol and ether. In the female, where cologne or alcohol would produce too much irritation of the sensitive mucous membrane of the vagina, or where the parts around the anus are involved, I have used a solution of two grains to six ounces water, washing the parts with vinegar to loosen the nits, advising that the garments worn next to the skin should be frequently changed and disinfected, that the parasiticide should be used for a few days after the trouble has disappeared. Where the limbs are hairy, they also should be examined carefully, as the parasite often appears there after it has disappeared from the part where it was first discovered. I have also found the parasite among the hairs on the armpits. Care should be taken in prescribing local applications of corrosive sublimate to ascertain if there are any excoriations of the skin present which would allow too rapid absorption of the drug. In that case a very cleanly method recommended by Dr. Cantrell of Philadelphia would be worth trying: "It consists in applying lint saturated with chloroform over the part affected, and covering it with oiled silk; this kills the parasite, and applications of vinegar will remove the ova."

Herpes progenitalis occurs frequently in persons with long and redundant prepuce, involving unusual irritability of the parts. In some cases circumcision has seemed to be necessary to prevent the frequent recurrence of the disease, but I have generally been able to relieve most subjects by the insisting upon absolute cleanliness and the application of the following lotion, suggested by Dr. E. L. Keyes:

℞ Listerin, Vin Aromatic } aa . . . . ℥ijss
Aquæ . . . . . ℥j

M. Sig.—Apply between glans and prepuce on a piece of cheese-cloth, changing the dressing after each urination.

I have also succeeded in hardening the parts affected, after the cure of the affection, by advising frequent ablutions and painting the parts daily with a solution of tannin and glycerin, one dram of the former to one ounce of the latter. In these cases, the herpetic vesicles sometimes rupture, leaving ulcerated cavities surrounded by some induration, and these I have treated successfully by applications of thioform.

Pruritus or itching, general and local, is an affection which we meet with very frequently in practice, and is very annoying to both patient and practitioner. To the patient it is most distressing, and to the practitioner it presents a difficult problem, in many cases, for solution in determining its cause, when we note that it is an accompaniment of most skin diseases, except the skin manifestations in struma, syphilis, and the exanthemata, although I have the history of one case of syphilitic general eruption in which itching was a marked symptom.

Among the palliatives for itching, I have found carbolic acid in the proportion of one dram to the half pint of water, with a little glycerin, and perhaps half a dram of potassa fusa, a most efficient antipruritic.

In general pruritis in cases of jaundice due to functional or organic disease, I have prescribed

one-tenth of a grain of hydrochlorate of pilocarpin, three times a day, with good effect. Warm baths, alkaline baths, bran-water, and inunctions with oil I have used as soothing applications.

Chloasma has been applied somewhat loosely to all brownish or yellowish-brown discolorations of the skin larger than freckles. They occur as a concomitant of pregnancy or uterine disorder, and sometimes in neurasthenic conditions, and after proper investigation and treatment of such troubles I have sometimes succeeded in removing the spots, temporarily at least, by causing exfoliation of the epidermis by lotions of corrosive sublimate, five to ten grains to the ounce, applied two or three times a day until the epidermis loosens; this may then be rubbed off.

In the treatment of scabies or itch, I have found the ointment recommended by Dr. Tilbury Fox gives the best results:

℞	Sulphur	ʒ ss
	Ammonio Chlorid of Mercury	grs. iv
	Creosote	gtt. iv
	Oil of Camomile	gtt. x
	Adeps	ʒ j
	M.	

This is rubbed in night and morning for three days, especially to the interdigits and wrists; the same shirt is kept on until the third day, when it is changed and a warm bath given. The parasiticide must not be used for too long a time. I have also recommended the use of powdered sulphur in the bed of the patient at night.

Phtheiriasis capitis is often discovered when least expected, on persons whose vitality is below par and whose scalps are not in a clean and healthy condition. The three remedies which I have found efficient in the destruction of these parasites and ova are: Carbolic acid, fluid extract of staphisagria, and dilute acetic acid. The carbolic acid I have applied as an ointment of the strength of ten per cent., and have found it especially efficient in promoting healing of the excoriations produced by scratching. I have used, as recommended by Dr. Cantrell of Philadelphia, the following:

℞	Fl. Extract Staphisagria	ʒ j
	Acid Acetic Dilut	ʒ iij
	M.—Apply thoroughly to the scalp.	

To promote a healthy condition of the scalp afterward, I have found resorcin a good local application, used according to the following formula: Five per cent. solution of resorcin in equal parts of alcohol and water, to which one dram of glycerin may be added.

Experience has taught me to watch for herpes zoster in patients who complain of obscure pains in the chest or abdomen. The etiology of the disease is so obscure and doubtful that it is difficult to name any efficient internal remedy. Since reading the paper of Dr. James M. Winfield of Brooklyn, regarding the malarial origin of zoster, I have prescribed quinin. Among local applications, I have found a preparation of sulphate of morphin, five grains to one-half ounce of collodion, a good protective and anodyne. For the neuralgia, I have used a pill consisting of one-third of a grain of phosphid of zinc combined with one-sixth of a grain of extract of nux vomica, given at the commencement of the attack and repeated every three hours. When this fails, morphin may be used.

Tinea tonsurans, or ringworm of the scalp, I have met with only once, and treated by shaving the hair and applying chrysophanic acid, seven grains, to one ounce of chloroform. The chloroform solution was well pressed and dabbed into the affected places with a minute sponge. The places should be well washed every morning with hot water and soap, to remove any sebaceous matter or crusts, and the hair should be kept closely cut on them till the new hair appears, which is generally in from two to three months.

As the sweat-glands are lined with epithelial cells, a faulty condition of such cells may have something to do with the disordered secretion. At any rate, with these views, we are warranted in administering such medicines and advising such measures as improve the general nutrition and tone, and applying such local remedies as will diminish the hypersecretion. Among the local remedies for accomplishing this purpose I have found belladonna, in the form of the tincture or the liniment, useful. Among internal remedies, those which are calculated to improve the condition of the nervous system would seem to be indicated, such as iron, quinin, strychnin, arsenic, and the hypophosphites. Sulphuric acid and atropin I have used with temporary benefit.

Dermatitis exfoliativa I have met with only once, occurring on the palmar surfaces of the hands and fingers. The patient was a carpenter and had suffered considerably from rheumatism. This case was characterized by redness and extreme tenderness and sensitiveness of the palmar surfaces of the hands and fingers, with desquamation or exfoliation of the epidermis, leaving a red and sensitive surface. A cure was effected by immersing the hands in warm water, about as hot as could be borne, two or three times a day, and the internal administration of Fowler's solution of arsenic.

THE MANAGEMENT OF THE SENILE HEART.

By JOHN W. BELL, M.D.,
OF MINNEAPOLIS, MINN.;
PROFESSOR OF PHYSICAL DIAGNOSIS AND CLINICAL MEDICINE, UNIVERSITY OF MINNESOTA.

Under the questionable title of "senile heart" I desire to call attention to a most interesting form of cardiac disease occurring in persons beyond middle life, especially in the decades between forty and sixty. The term "senile heart" is a most unfortunate one, inasmuch as it is used in an indefinite way by many physicians and writers, to include all cardiac changes of a chronic character in old or even middle-aged people who look senile. In this paper the term "senile heart" will be used in its restricted sense, hence, not including on the one hand previously existing valvular disease, or on the other those pronounced cardiac changes due to general arterial fibrosis, atheroma, or renal disease.

In order to make more clear the morbid condition to which the term "senile heart" is herein applied, permit me to call your attention briefly to the more constant or normal changes occurring in the heart—the result of advancing age. Every healthy individual starts on life's journey with a balance to the credit of his heart—the extent varying in different individuals; this balance we designate as reserve compensatory force. Hence, we are not surprised, on examination, to find the heart showing evidence of slight hypertrophy beyond middle life. This enlargement would seem but the logical outcome of the increased labor forced upon the heart by changes in the arteries, capillaries, and extravascular tissues, the result of age. Bizot and Balfour believe this change to be universal in all old people. From clinical investigation I am convinced of the truthfulness of this statement in the vast majority of cases. This slight enlargement is of gradual growth, unaccompanied by symptoms, and hence should be looked upon as a conservative or beneficial change. As long as the heart muscle maintains its integrity, all goes well with the individual; but if from any cause the innervation or nutrition of the myocardium be seriously interfered with, thus unfavorably modifying the normal senile enlargement, evidence of myocardial weakness accompanied by dilatation of one or more of the cardiac cavities soon appears, leading to grave embarrassment of the heart and circulation. The essential lesion is then a weakened myocardium, accompanied sooner or later by dilatation—the result not of inflammatory or degenerative changes, but of disturbed innervation or defective nutrition, arising from the many causes operative during and after middle life. These causes are so numerous and varied in character as to preclude more than a brief reference to them in this paper.

Among the more frequent causes of disturbed innervation may be cited the abuse of alcohol, tobacco, tea, coffee, sexual excesses, business or domestic worry; in fact, any cause, physical or emotional, if sufficiently violent or prolonged, may interfere with the innervation of the heart as evidenced by an irregular or intermittent pulse. Among those causes tending to interfere more directly with the nutrition of the myocardium may be mentioned anemia, hydremia, gout, dyspepsia, etc. As clinicians, we are all familiar with the following group of symptoms, constituting a clinical picture met with frequently in the examination of persons beyond middle life. An active business man beyond middle life, of good habits, previously free from any evidence of cardiac disease, begins to suffer from breathlessness on the slightest extra exertion, and from precordial discomfort and distress at intervals. His pulse becomes slightly irregular in rate, rhythm, or force, perchance intermittent. Slight overwork or worry precipitates an attack of palpitation; he becomes painfully conscious of the presence of a heart; consults his medical attendant, who finds, on examination, the following signs: A weak, almost imperceptible cardiac impulse located in or near the left nipple line. On careful percussion, the deep cardiac dulness is found to be slightly increased. On auscultation the heart sounds early may be normal, later, the first sound becomes shorter and weaker, accompanied by a faint systolic murmur, audible at the apex and frequently over the pulmonary area, if the left auricle be enlarged. A slight accentuation of the aortic second sound being the rule after middle life, I have seldom observed that sharp accentuation of the aortic second sound described by Balfour, which he ascribed to dilatation of the ascending portion of the aorta, but have frequently observed a short, faint, systolic murmur over the aortic area, faintly transmitted along the vessel, due, I believe, in the majority of cases, to dilatation of the ascending portion of the vessel. This clinical picture is but the reflex of a weakened myocardium, accompanied by dilatation of one or more of the cardiac cavities, which condition, if not recognized and relieved by proper treatment, soon gives rise to grave changes in the heart. These changes become apparent in the enlarged percussion area and by the presence of murmurs over the several valvu-

lar areas, accompanied, or soon followed, by all the unpleasant symptoms of cardiac failure, soon ending in death.

For the purpose of treatment, we may divide the clinical course of the disease into two periods or stages. First, the period of progressive and often slow development of myocardial weakness, accompanied by breathlessness, precordial distress, irregular pulse, and occasional attacks of palpitation. Second, the period of advanced myocardial weakness, accompanied by marked symptoms of cardiac insufficiency, such as constant precordial distress, dyspnea, frequent attacks of palpitation, marked irregularity of pulse, tachycardia, bradycardia, angina, and later, all the symptoms of general venous engorgement, ending fatally if uncontrolled.

The first period requires principally hygienic, dietetic, and general tonic treatment—our efforts being directed toward making the cardiac muscle equal to its task and to maintaining its integrity. Each individual case should be carefully studied, an accurate diagnosis being the first essential to successful treatment. Having then a clear conception of the patient's condition, it should be carefully and frankly explained to him, unless there be special reason to the contrary, when it should be explained to a friend or relative. The patient must be made to understand why he is to follow instructions explicitly, and informed that if he transgresses, his sin will manifest itself in more frequent and severe attacks of precordial distress, dyspnea, palpitation, and, perchance, angina. Having secured the confidence of the patient, our first endeavor should be to discover and remove every possible cause of cardiac irritation and embarrassment. Our second endeavor should be to so regulate the diet, exercise, and habits of the individual as to bring the general nutrition, as well as that of the heart muscle, up to the highest possible point and maintain it. For this purpose, in addition to hygienic and dietetic measures, general tonic treatment, consisting, according to indications, of iron, strychnia, arsenic, and bone-marrow will be found necessary. The patient should be advised to eat and sleep regularly, using three meals daily, composed of nutritious food suited to the requirements of his special case—the midday meal always being the principal one—no solid food being allowed between meals—little or no fluid with meals. The lungs should be supplied with a liberal diet of oxygen, hence the sitting and sleeping apartments of these patients should be well ventilated—tent-life being the ideal one; they should be urged to sleep at least ten hours out of every twenty-four, with a midday rest in the recumbent position of at least one hour following the principal meal, in order to minimize the daily labor of the heart; the latter injunction should be rigidly followed the remainder of the patient's life. The question of exercise must be carefully considered in relation to each individual case and with special reference to the condition of the myocardium. However, in the large majority of cases of "senile heart" absolute rest in the recumbent posture will be found necessary for a time at least. The patient's habits should be carefully regulated—tobacco, alcohol, tea and coffee should be interdicted. They should be urged to lead a quiet, orderly, and temperate life, as free from worry and excitement as is compatible with our modern civilization. Our resources will be sorely taxed in our endeavor to regulate the habits of senile patients. Yet, it is attention to the little things of eating, drinking, and doing, which makes success possible in dealing with this condition. How futile to attempt to restore the dilated heart of the tobacco fiend, opium-eater or alcoholic unless he forswears the habit.

Unfortunately, these patients do not present themselves for treatment until marked weakening of the myocardium has occurred, indicating the second or advanced stage of the disease. We are then confronted with the difficult problem of medicating a weak and dilated heart in an individual having, by virtue of his age, suffered certain vascular as well as extravascular changes, causing increased intra-arterial and cardiac blood pressure. Hence the condition of the circulation as indicated by intra-arterial and cardiac pressure, becomes the key to successful treatment.

For the relief of the more or less constant high intra-arterial pressure, we rely largely on the iodids and nitrites. I have found the iodid of sodium in from three- to five-grain doses, repeated three times daily, of marked benefit in dilating the arterioles, thus reducing intra-arterial pressure, the iodids having a much more prolonged action than the nitrites, are to be preferred for internal administration. The digitalis group, consisting of digitalis, strophanthus, strychnia, caffein, spartein, etc., render most excellent service in giving tone to the weakened myocardium, when combined with vascular stimulants like the iodids and nitrites.

In the management of pronounced senile cardiac insufficiency, no method of treatment has proven so eminently satisfactory in my hands as

that of subcutaneous medication, assisted by rest, baths, saline cathartics, Swedish movements, and massage. During the past three years, it has been my pleasure to see many cases of advanced cardiac dilatation respond to strychnia, digitalin, nitroglycerin, etc., hypodermically administered, which would otherwise have died under any other treatment at my command. In order to secure the best possible results, strychnia, digitalin, and nitroglycerin, should be combined for a time, later, omitting the digitalin, or using it interruptedly, according to indications—in every case increasing the dose of strychnia until it produces muscular twitching, and there maintaining it. The smallest dose of nitroglycerin capable of producing the desired dilatation of arterioles should be the rule. It has been my custom to begin with the 1–40 of strychnia, used every six or eight hours, gradually increasing the dose until its characteristic muscular manifestations appear, always combining it with nitroglycerin, and adding digitalin as indicated. Subcutaneous medication is especially indicated in the aged, owing to their naturally feeble gastric absorption, but more especially in the management of cardiac dilatation, owing to the accompanying gastric catarrh resulting from venous engorgement. It is urged against the subcutaneous method of treatment, that it requires the presence and expense of a trained nurse; on the contrary, any intelligent person can be quickly trained to use the hypodermic syringe, thus enabling the physician to carry out the treatment at the patient's house without additional expense.

In suitable cases, saline baths of a suitable temperature are an efficient aid in freeing the periphal circulation, thus relieving venous engorgement and its attendant ills. I begin with a bath of ten minutes' duration, the bath to consist of forty gallons of water at a temperature of 100°, gradually lowered to 92°, holding in solution 4½ pounds of chlorid of sodium. This is repeated daily for some days, then less frequently, gradually increasing the amount of saline, as well as the duration of the bath, from day to day, until the patient remains in the bath at least thirty minutes. I have never observed any unpleasant effects; on the contrary, patients have expressed themselves as feeling relieved and refreshed. During the bath, the pulse becomes slower and fuller, the respiration slower and deeper, and the cardiac impulse stronger and more circumscribed, with apparent at least temporary decrease in the transverse cardiac dulness. Massage and Swedish movements, properly applied, are useful aids in improving the circulation—the latter in the form of movements of resistance being of especial advantage, owing to the feeble muscular movements and sedentary habits of senile patients. Saline cathartics cautiously employed are especially useful in relieving the more or less constant gouty condition present after middle life; later, they prove invaluable in removing dropsical accumulations.

We thus see that the clinical history of the "senile heart" is not the story of a few weeks, or even months, but often comprises the life history of the individual in respect to heredity, habits, etc. Consequently, in this struggle with mortality—for it should be constantly borne in mind that we are dealing with an incurable condition—we should endeavor by careful investigation to search out and remove every possible cause of cardiac irritation and embarrassment, our time and labor being richly rewarded by the knowledge that we can, in the majority of cases, add years of confort and usefulness to the individual's life.

In conclusion, I desire to emphasize first, the necessity, yea, the obligation for early and prompt recognition of the danger signals indicative of beginning senile cardiac insufficiency, believing that no practitioner is justified in ignoring or passing as unworthy of therapeutic attention, the breathlessness, precordial distress, and irregularity of pulse so often encountered after middle life; second, to urge especially upon the profession the more general use of the subcutaneous method of treating cardiac insufficiency.

SOME THOUGHTS ON THE ORIGIN AND SPREAD OF CONTAGIOUS DISEASE.[1]

By W. H. FAULDS, M.D.,
of Luzerne, Pa.

Aside from aseptic and antiseptic surgery there is, perhaps, no subject in which, at present, the laity and medical profession are taking greater interest than the origin and spread of contagious and infectious diseases.

With the advent of antiseptic surgery came the germ-theory of disease, and the theory of contagion and infection through microörganisms, and in this way was developed a force which has revolutionized surgery, and set at naught almost every principle upon which the leaders in sanitary and medical science had for centuries based their teachings and investigations. That such a radical change in the fundamental principles of these great factors in the world of science should work a cor-

[1] Read before the Luzerne County Medical Society.

responding change in the means used for the prevention and spread of contagious diseases goes without saying, and that the laity, physicians, and sanitarians should be tardy in adapting themselves to the new order of things, is what might be expected. However, we believe the time has come when we, as physicians, ought to be preparing ourselves to measure up to the standard required by the new régime, and thus escape the censure which is sure to come from a confiding public, if we prove recreant to our trust. But in order that we may be successful, we must first have a clear conception of the principles which are to guide us in our efforts.

A moment's consideration of the subject teaches us that almost all the vital processes are based upon the principle of supply and waste, and that waste material or filth becomes a source of disease only when misappropriated or diverted from its proper channel. In other words, the waste matter of animal life, if not properly appropriated, furnishes a hotbed for the reproduction of microorganisms, which are now recognized as the chief factors in the production and spread of contagious diseases. The land and city refuse, swept into our rivers, furnishes pabulum to the finny tribe, and they in return supply the most delicious meats to the inhabitants of every clime. But not only does the refuse contribute to the maintenance of all animal life, but the lower order of animals are sacrificed that the higher may subsist.

It is also true that this higher order may become the easy prey of the microscopical world, being sometimes swept down upon by an army of these minute invaders, their onslaught being more deadly than that of the best disciplined soldiery armed with the most approved weapons of modern warfare. But besides being the avowed enemies of the human family, vulture-like, these infinitesimal wonders are ever on the alert, watching for the first symptoms of decay, always ready to assert their prerogative whenever a soil favorable to their development and propagation is spread out before them. Unlike the human family, that select the best in the line of animal and vegetable foods for their sustenance, these disease-producing organisms revel only in tissues of low vitality, caused either by temporary departure from health, or the incipient stages of the process of degeneration and decay.

So intimately associated are they with the higher forms of life that they are found everywhere, even occasionally in healthy tissue. "They exist in the air, the soil, the water, in our clothing, on the surface of our bodies, and on the mucous membrane of the intestines, and respiratory tracts." But as we have already intimated, it is chiefly in decaying organic substances that they find a soil most favorable to their propagation and development. It is this special affinity of bacteria for animal tissue that has given origin to all the contagious and infectious diseases. Thus in scarlatina, diphtheria, measles, smallpox, typhoid, whooping-cough, and a host of other affections, we find in each its peculiar disease germ, each having distinguished features as familiar to the bacteriologist as the different types and races of the human family.

The question is sometimes asked: "Where did the first case of contagious disease originate?" One answer to this question is, that until spontaneous generation is proven and life shown to be the result of physical forces, these microörganisms, capable of reproducing themselves, must rank with the higher orders of organic life, whose origin can only be traced to Him who, in the beginning, created all things. If the smallest germ of animal or vegetable life may be the product of physical forces, then all life, yours and mine included, may be the result of forces in nature, and we need no longer look to a Supreme Being to solve the mystery of the origin of life.

By assuming that the pathogenic germs had their origin with other forms of organic life, the question as to the origin of contagious diseases still remains unanswered, and the only explanation we have to offer is, that the first case of contagious disease was caused by the presence of virulent bacteria in human tissue of lowered vital resistance, and that the pathogenic bacteria were made such by cultivation in a favorable medium, furnished by the habits and environments of man at some period in the history of the human race. That the virulent bacteria were not, in their pristine state, capable of producing smallpox, diphtheria, scarlatina, cholera, and syphilis, seems reasonable from the fact that these diseases are spread only by contagion or infection from a previously existing case, and that these diseases can be clearly traced to the countries in which the primitive germs were first made pathogenic. Again, it would be hardly fair to assume that these countries were exceptions to the rest of the earth's surface in the matter of containing these germs, and that primitive man took up his abode in the only countries fruitful of diseased germs, and which have since given as a legacy to his posterity almost every pestilential disease to which human flesh is heir.

To me, then, a logical inference is, that bac-

teria are present with the other forms of organic life in all parts of the habitable globe, and that all that is required to make them pathogenic is the favorable conditions which developed cholera and other germs in the countries where they first made their appearance.

The argument then is, that the conditions favorable to arousing the microbe to a state of activity must exist before the disease can make its appearance. But the bacteria, once active, act in the presence of conditions that could not arouse the microbe from its dormant state. To illustrate: cholera, so far, has failed to gain a foothold in this country because the conditions here are not such as to arouse the dormant germ. However, the active bacillus from abroad, that has become virulent from repeated multiplication in a favorable soil, produces the disease here in its fatal form among the susceptible, just as it does in the older countries. The same, I believe, is true of scarlatina, smallpox, measles, and diphtheria. Diphtheria was known and described by Galen. Memorable epidemics existed in Rome as early as A.D. 856, but it was not until eight hundred years later that this disease made its appearance in Switzerland and Germany, a century later in Naples and in our own country.

So of scarlatina, although known as early as the first century of the Christian era, it was first described by an English physician in the sixteenth century, and extended to the western world through European shipping in 1735, to Iceland in 1827, and to Greenland in 1847, showing conclusively that this germ, like diphtheria, was fostered and brought to a state of virulency still unknown to us, by the people who, in a state of ignorance and religious lunacy, looked to their gods for relief, while they themselves were violating every principle of the laws of health. Again, smallpox was first mentioned by an Egyptian physician in the sixth century, and undoubtedly this germ owes its extreme vitality to the favorable conditions under which it was aroused into activity, and its virulence developed.

So we might mention other diseases which exist here, but from which we would never have suffered had they not been brought to us from these disease-breeding countries, because the conditions here have, so far, not been such as to arouse the dormant germ.

Prior to the discovery of Koch, there were many theories extant regarding the spread of contagious and infectious diseases, none of which, however, receive confirmation in more recent investigations. But now the generally accepted theories are those of this great leader in scientific thought. And as his investigations have shown that all contagious diseases are dependent upon the presence of a microörganism, capable of self-propagation, the theory that every case of contagious disease must have had its origin in a previous case, at once became tenable.

This theory, however, was advanced by medical writers prior to the investigation by Koch of the germ theory of disease. Macnamara, in his discussions on cholera, says: "No amount of overcrowding, no special condition of the soil, nor any circumstances with which we are acquainted has ever been known to originate Asiatic cholera *de novo* among men removed from its endemic influences, or unless the disease has been epidemic beyond the confines of India." Again, he says: "Every outbreak of the disease beyond the confines of British India may be traced back to Hindostan, through a continuous chain of human beings affected with their dejecta."

In 1881, Wilson of Philadelphia, said of typhoid fever: "Without doubt the fever-producing principle is an organic germ, a *contagium vivum*, and is invariably derived from a previous case of enteric fever."

Macnamara also states in his discussions that "the more explicit the examination, the clearer the fact appears that the disease (cholera), in the majority of cases, spreads from one human being to another by means of the cholera fomes finding its way into the drinking water, and thus into the intestines of other people."

"I by no means deny," said Pettenkoffer, "the transmissibility of cholera by means of man coming from an infected place. I consider man alone as the specific cause outside the influence of the infected locality; moreover, I consider him the propagator of cholera, when he comes from a place where the germ of the disease exists."

What is said of cholera, we believe, upon investigation, will prove true of scarlatina, diphtheria, smallpox, and tuberculosis. We have ample proof that these diseases had their origin in the Old World, and were in all probability spread only through human intercourse.

Diphtheria was first brought to the United States through European shipping, and made its first appearance in Boston in 1735. "Thence it extended westward over the British colonies, reaching the Hudson and New York in two years, and after a time leaped over the barrier of the river. It gradually disappeared, attracting no further attention, except as a historical fact, noted by Douglas, Bard, Colden, and others."

Scarlet fever also had its origin in the Old World, and in its spread has been subject to the same laws regarding human intercourse as the other diseases mentioned. Again, tuberculosis, although known to the inhabitants of every clime, undoubtedly spread like cholera, syphilis, and diphtheria, from the thickly populated centers of the Old World, and is spread only, directly or indirectly, from animal to animal, or from man to man. That up to a few years ago there were isolated spots on the earth's surface that its virus had not penetrated, is rendered possible by the statement of Gibon, in the *Annual* for 1890. He says: "According to Certes there are no pathogenic microbes to be found at Cape Horn. The Fuegians did not know anything about smallpox, measles, scarlet fever, or diphtheria, before the inroads of civilized nations. Prior to the visits of the missionaries even pulmonary phthisis was unknown, and tuberculosis only began to establish itself in that country since 1881." It is said of the North American Indian that, before the discovery of America by Europeans, he was entirely exempt from the pestilential diseases. He had, in his primitive state no ailments, so far as we can ascertain, except such as were incident to exposure and old age. The gold hunters are said to have introduced smallpox into Mexico, and the adventurers from the Old World brought with them the eruptive fevers and loathsome contagious diseases of vice and immorality.

A French writer is authority for the following statement: "A soldier returned home consumptive, after undergoing confinement in a Prussian military prison. Previous to his return no one in the village had for many years suffered from consumption. He expectorated freely, and it was observed that the fowls swallowed the expectorated matter. These fowls were given to a woman in the village who was in perfect health, and in the course of four months she consumed sixteen of them. She had no direct communication with the patient, but after a time became consumptive. One of the fowls was killed and tubercle was found in the liver and other organs."

Again, it is said of cholera that the germs cannot retain their virulency long outside of human tissue. Thus, Pollock found that after each invasion or epidemic the germs died out, and with each recurrence there was a new importation of germs. This would account for the disappearance of the disease in this country after the epidemics which have several times visited us. That this is true of diphtheria, scarlatina, and smallpox, remains to be proven, but would appear probable from what has been said of the first epidemic of diphtheria in this country. That the germs must have lost their disease-producing qualities appears from the fact that the inhabitants were free from the disease from 1735 to 1835, a period of about one century.

This disappearance of the disease germ, unless a fresh supply is received from human tissue, would seem to be in accordance with a law of the animal and microscopic world, that neither can exist long in the presence of the poisons of its own excretions. Thus we find in the overcrowding of human beings in jails, barracks, and camping grounds, unless protected, they soon die of diseases produced by their own emanations. So the bacteria cannot long survive in the poisons which result from their presence in large numbers.

If, then, every case of a contagious and infectious disease has its origin in a previous case, and is spread directly or indirectly through human intercourse, and the germs of this disease die unless reinforced from animal tissue, it is certainly fair to assume that if all the disease-producing organisms could be prevented from attacking animal tissue, it would not be long before the virulent germs would have to return to their primitive dormant state for want of nutritive pabulum, and then would the declaration of Pasteur be verified, "That it is within the power of man to cause the parasitical diseases to disappear from the world."

If the principles here laid down are accepted as a working hypothesis, the destruction of the virulent bacteria by isolation, quarantine, and disinfection, must form the basis of our efforts to prevent the spread of contagious and infectious diseases. But all medical writers are not in accord on this subject.

Pettenkoffer, who has given us an extended array of works on cholera, says: "Too much importance has been given to bacteria as an etiological factor in the spread of cholera, and the importance of local conditions has been overlooked." He tried to prove his position by taking into his system the cholera bacillus; the cholera bacilli were found in his stools for eight or nine days after ingestion, but his health was not seriously affected. He is also strongly opposed to quarantine, and says that the spread of the cholera germ is not to be prevented, either in India or outside of it, by isolation, quarantine, disinfection, etc. He further says: "Just as in spite of custom houses, goods are still smuggled over the frontiers, so the bacteria and viruses will be smuggled through all our barriers." He re-

gards the millions expended in hunting down the germs as wasted effort, which should be diverted to the work of making people and places immune. I have cited this authority more to show how easy it is for eminent men to give adverse views concerning precautionary measures which sanitarians of equal eminence, after a long struggle, have barely succeeded in establishing.

The importance of isolation has long been recognized. A century ago Naples fined and even imprisoned her physicians for failing to report to the authorities cases of tuberculosis, the result being a reduction in the mortality from this disease of ninety per cent.; and despite the fact that at a later period these measures were abandoned, under the impression that this disease was not contagious, recent experience argues that isolation affords the only practical solution of the question of how to prevent the spread of this most fatal of all maladies.

It is said of England, that within the past few years, through improved hygienic conditions and isolation of the tuberculous patients, the mortality has been reduced fifty per cent.

Philadelphia, during the past eight years, has reduced her mortality from phthisis twenty per cent. California, in view of the fact that it is rapidly becoming the great sanitarium for these unfortunates, is seriously considering the importance of the isolation of phthisical patients in order to prevent the spread of the disease.

I need not quote authority to convince you of the importance of this measure in the prevention and spread of diphtheria, scarlet fever, and the other contagious diseases.

A question of more practical importance is, what are we doing to prevent the spread of disease? Our answer is nothing compared to what ought to be done. I would not for a moment disparage the work of our State Board of Health, or the efforts of our local boards. They are probably doing all in their power, considering the means at their disposal, and the niggardly policy of our legislature by which they are handicapped. But I am convinced that nothing worthy of the effort will be accomplished until every person and animal threatened with, or sick of, a contagious disease can be isolated and thorough disinfection practised under the care and direction of a competent bacteriologist. If, as we have argued, a virulent disease germ is abroad and cannot be destroyed so long as it can find a favorable soil for propagation in human or animal tissue, anything short of complete isolation will be wasted effort.

So far we have said nothing of what is being done by inoculation to render persons immune, or prevent the spread of disease. If we were to judge of the value of this method of preventive treatment by the newspaper notoriety antitoxin has received, it would indeed be a great boon to humanity, but, as you know, the results thus far have been disappointing to the medical profession, and even if man could be rendered immune, the exceptions would be so numerous as to make it unsafe to depend on that alone.

Much of late has been said of increased vital resistance as a preventive against the invasion of virulent microörganisms. In those predisposed to tuberculosis, this is undoubtedly an important factor. But in cholera, smallpox, diphtheria, syphilis, and scarlet fever, comparatively healthy persons are attacked, and if nothing in the physical condition or hygienic surroundings of the human family, at the present day, can produce the disease without the specific germ, as it has come down to us through propagation in human tissue, vital resistance would be of secondary importance compared to isolation, disinfection, quarantine, etc. If these measures were faithfully carried out, there would soon be no germs to attack even tissue of lowered vital resistance, unless the conditions of the Old World, by which they were first aroused from their dormant state, were recurrent. The results obtained by vaccination in smallpox would seem to encourage a trial of this method of preventive treatment in other diseases, but we must not forget that while vaccination was a great discovery, and has done much to prevent the spread of smallpox, we are also very largely indebted to isolation, quarantine, and disinfection, for the immunity we enjoy from this disease. Indeed, I believe it fair to assume that had it not been for the increased immunity made possible only by isolation and quarantine, mankind would have long ago lost confidence in the protective power of vaccination, and abandoned it as a useless procedure.

That there are almost insurmountable difficulties in the way of carrying out the measure proposed for the prevention of the spread of disease we frankly admit, but, nevertheless, the fact confronts us, that unless we can prove the correctness of our theories by the results obtained, the laity will soon lose confidence in our teachings, and refuse to coöperate in our work, and what has been regarded as the greatest discovery of the age—the transmission of disease through microörganisms — may pass into oblivion, because of the stupidity of the laity and the want of faithful, persistent, courageous effort

on the part of sanitarians and the medical profession.

A summary of our "thoughts" then is:

1. That non-virulent microbes exist in all parts of the habitable globe.

2. That they were made disease-producing in the case of cholera, smallpox, syphilis, diphtheria, and tuberculosis, in the thickly populated centers of the Old World through overcrowding, and bad hygienic conditions, such as have never been known to us.

3. That the virus is always derived from a previous case, and is spread, either directly or indirectly, through human intercourse.

4. That increased vital resistance renders persons immune only in tuberculosis and other exceptional instances.

5. That if virulent bacteria could be prevented from finding a lodgment in human tissue, they would, for want of nutritive pabulum, soon return to their primitive dormant state.

6. That isolation, quarantine, and disinfection, under the direction of bacteriologists, are the only means by which we may hope to successfully prevent the spread of contagious and infectious diseases.

CLINICAL MEMORANDA.

A CLINICAL VIEW OF PYELITIS, WITH REPORT OF A RECENT CASE SUCCESSFULLY TREATED BY INCISION AND DRAINAGE.[1]

By J. HOWELL WAY, M.D.,
OF WAYNESVILLE, N. C.

PYELITIS is the name given by R. Ayer to inflammation of the pelves of the kidneys and of their calices. The disease may affect one or both kidneys, it may be acute or chronic in its course, but like the majority of genito-urinary disorders encountered in practice, is usually subacute or chronic, undergoing, perhaps, from time to time acute exacerbations. In simple catarrhal inflammation the mucous lining of the renal pelves is reddened, swollen, and pours forth an abundant secretion containing pus-corpuscles, epithelial cells in varying quantity, and occasionally also blood-corpuscles. In more severe types, met with almost solely as a complication of other pathological conditions, an actively purulent or ulcerative inflammation may exist. In chronic pyelitis the mucous lining of the pelves is thickened and its surface studded with small vascular granulations; the pelvis, infundibula, and ureter are also thickened, and usually dilated as well. Pus is freely poured forth and, if the patency of the ureter be maintained, escapes with the urine. Should an obstruction take place in the ureter, as frequently occurs from the thickening of its walls, or from coagulated blood, or thickened flocculi of pus, from calculi or from the presence of parasites, it accumulates in the pelvis, distending it more and more, and giving rise to a condition known as pyonephrosis. This process of dilatation, as it increases, encroaches first upon the papillæ, flattening and eventually obliterating them. Later the pyramids are subjected to the same pressure and atrophy, and finally, when the pelvic dilatation has existed for some time, the cortical portion of the kidneys disappears. In such cases we have only a sacculated pouch remaining, which contains from perhaps only one to many ounces of fluid, often mixed with inspissated pus, products of ammoniacal decomposition, calcareous matters, and calculi. If the pyelitis has been secondary to renal calculi, as it frequently is, there are also apt to be present more or less extensive ulcerations. Perforation of the renal pelvis sometimes takes place, with resultant extravasation of its contents into adjacent tissues or organs. The perirenal tissues, the bronchi, the pleural cavities, the intestine, the bladder, the structures immediately behind and below Pouparts' ligament, and, rarely, the peritoneal cavity are all possible sites for the discharge of the secretions of a perforated pelvis. In cases of pyelitis of long standing we not infrequently have developed from an increase of interstitial connective tissue and an atrophy of renal tubules a condition of contracted kidney differing perhaps but little, save in its etiology, from the cirrhotic kidney of certain types of Bright's disease.

Probably first among the causes of pyelitis is the extension of a diseased condition from the bladder along the ureter to the kidney. Whatever produces retention of the urine may set up cystitis, with its concomitants, fermentation and decomposition of urine, and then later, if the cystic disorder continues, extension along the ureters to the renal pelves. It is the cases of pyelitis from this cause which are so prone to degenerate into pyelonephritis or surgical kidney—the pelvic inflammation induced by microbic action involving the proper tissue of the kidney itself. Potent among the influences in bringing about these results are gonorrhea, stricture, prostatic disease, pregnancy, abdominal tumors, vesical paralysis, etc. The irritation of renal calculi or of other foreign bodies in the kidney-pelvis is a frequent cause of pyelitis. Specific influences, as tuberculosis or rheumatism, at times act as causes. It may be a complication of typhoid fever, pneumonia, scarlatina, diphtheria, and smallpox. Traumatisms, blows, or contusions in the iliocostal region may be the causative factors. The irritant action of a hyper-acid urine or of the overuse of diuretics of the stimulant kind, copaiba, turpentine, or cantharides, may set up a catarrhal pyelitis. A primary pyelitis or pyelonephritis, coming on after over-exertion or exposure to cold, and without any of the above causes apparently being in operation—idiopathic pyelitis—has been described by a few writers, but its existence is denied by the majority of medical authorities; yet I am convinced that we do meet at times with such cases. In this class I have placed the case herein reported.

The mild catarrhal cases occuring in conjunction with the specific fevers are, as a rule, devoid of very pronounced

[1] Read before the North Carolina Medical Society, May 14, 1896.

symptoms, and doubtless in the great majority of instances pass unrecognized, the pain in the back, if present, and modified urine being referred to other causes. Pain in the back, deep-seated, usually limited to the affected side where the disease is unilateral, aggravated by pressure and exercise, is generally present, though in occasional cases this symptom is absent. Where renal calculi are present, attacks of nephritic colic are experienced from time to time. In some cases, without the presence of stone there occur attacks of paroxysmal pain having all the typical features of nephritic colic. The secretion of urine is increased, and early in the disease contains blood-corpuscles, albumin in moderate or small amounts, and an abundance of small round or oval spindle-shaped or irregular epithelial cells thrown off from the renal pelvis. Only a few years since it was claimed that there were certain peculiarities about the pelvic epithelium—the so-called "tailed epithelium"—which rendered the diagnosis of pyelitis certain. The recent careful and painstaking investigations in the laboratory of Professor Satterthwaite have conclusively demonstrated the impossibility of basing a positive diagnosis of pyelitis upon anything found in the urine with a microscope. Later in the disease this profusion of epithelial cells is replaced by pus-corpuscles, which are evenly distributed throughout the urine, giving it a uniform turbid appearance when voided. On standing, the pus settles into a dense greenish oily-looking deposit. The specific gravity of the urine varies from 1025 to 1030, and is from first to last, as a rule, uniformly acid. Occasionally the pus disappears entirely from the urine for a few days, then reappears in increased amount, this being usually due to temporary occlusion of the ureter of the diseased kidney. Exercise increases the volume of pus. Where the ureter becomes occluded, we not infrequently have some swelling developed in the iliocostal space. The prominence of this swelling varies from time to time. When the ureter is open it may quite disappear; the ureter becoming plugged again with pus, blood-clot, or stone, the swelling promptly reappears. The pain in the back is usually greater when the swelling is prominent and pus is not flowing freely. Frequent micturition is usually met with in pyelitis, and when this symptom is pronounced, in the absence of pain, tenderness, or tumor in the loin, errors in diagnosis may readily occur. This tendency to frequent micturition in pyelitis is present as a reflex symptom, even in those cases where the bladder itself is unaffected. Suppurative pyelitis, whether occurring idiopathically or as an intercurrent affection, is usually ushered in with more or less pronounced chilliness, followed by fever. This tendency to rigor is apt to recur, assuming at times a quotidian or tertian type, in which event the disorder may be mistaken for malaria. When the pyelitis is bilateral, a subnormal temperature, according to Tiffany, is frequently noted. Later the fever assumes a hectic form and the general clinical picture of prolonged suppuration is presented. The clinical course of some cases, more especially those of tubercular character, resembles very much that of typhoid fever. In rare instances cases are seen which show pyuria present, with possibly slight tenderness over the kidney from time to time, without the supervention of serious constitutional or local symptoms. The appetite is apt to be poor—at best capricious—the digestion impaired, and the bowels alternating from constipation to diarrhea. Exceptionally the decomposition of urine and absorption of ammoniacal products give rise to the development of a train of obscure nervous symptoms similar to those presented in the last stage of diabetes. In this connection it is well to bear in mind the possibility of uremic symptoms arising.

Suppurative pyelitis is frequently confounded with cystitis. The two conditions may coexist in the same patient, but if carefully noted, the history of the case, the acid character of the urine, the less frequent occurrence of alkaline decomposition, the pain and swelling in the loin, the absence of vesical pain, would usually suffice to differentiate the two conditions. In perinephritic abscess neither pus, blood, mucus, epithelium, nor albumin are found in the urine; in pyelitis all are present. In perinephritic abscess, motion is much more painful and the patient, as a rule, is unable to straighten perfectly the affected side, the leg being held in the position of that of a patient in the first stage of hip-joint disease.

The *prognosis* in a given case of pyelitis will depend most, perhaps, upon the exciting cause. In simple catarrhal cases developing in connection with constitutional disorders, the prognosis is good. If the disease be limited to one side, recovery is possible, no matter how serious the lesion. Affecting both kidneys, the prognosis is unfavorable. Occuring as a secondary affection to prostatitis, cystitis, urethral stricture, it is necessarily considered serious. Dependent upon a renal calculus, hydatids, cancer, or tubercle, we can but view it with concern. When pyonephrosis is present, the condition becomes grave; pressure-atrophy may destroy the kidney, or fatal rupture may take place.

The *treatment* of pyelitis will depend largely upon the causes inducing the disease. During an acute attack attended with fever, severe pain, and frequent passing of bloody and purulent urine, attention to the *primæ vie*, with an opiate to allay spasm, warm diluent drinks, hot baths, hot local fomentations or wet cups over the affected kidney will meet the more prominent indications for treatment. Lithia waters have been highly extolled by some physicians in pyelitis. Alkaline and antiseptic diuretics are probably productive of beneficial results in these cases. In chronic cases, and it is this class that are seen, or at least diagnosed, most frequently, where there are reasons to suspect the possible presence of stone or other conditions which may at any time induce obstruction to the flow of urine, every effort should be made to counteract with suitable regimen, diet, and tonics the tendency to asthenia. The patient's symptoms and the local conditions should be noted most carefully, and if, after a short time, the indications of disease continue and the local conditions are unimproved, I believe it is then our duty to cut down upon the kidney and drain it. The use of the aspirator as a means of treatment is mentioned only to condemn it, increasing observation convincing me there are very few conditions of the human body where the scalpel cannot be more advantageously used than the as-

pirator. I desire to direct your attention briefly to a case recently operated upon with successful results:

On December 20, 1895, I was consulted by my friend Dr. Wilson, of Sonoma, who gave the following history of his patient, presented a specimen of the urine, and requested my assistance in diagnosis and treatment: B. B., a tall, angular, robust mountain farmer, aged thirty-eight, six or seven weeks previously after working very hard and exposing himself, was taken with a pronounced chill, followed by fever. Great pain and decided tenderness were early experienced in the left iliocostal space. The urine was voided frequently, and was often bloody and purulent. Chilliness from time to time continued with an intermittent type of fever. He became reduced in flesh and experienced night-sweats. The urine continued as before. Sometimes the Doctor thought there was possibly a small tumor in the region of the left kidney, at others he was not so sure of it, and even doubted the existence of any. I found the urine distinctly acid in reaction, albuminous, loaded with pus, blood, and epithelial cells. A probable diagnosis of suppurative pyelitis was made, and an operation suggested. January 11, 1896, I was summoned to see Mr. B., who told me that he had finally "consented to be cut, if it could be done without taking anything"—meaning an anesthetic. He was quite reduced in flesh; pulse 126; temperature, at 3 P.M., 102.6°. Dr. Wilson stated that the same symptoms as previously detailed had continued present. The patient was placed upon the table, and as careful preparations were made as would be possible in a mountain cabin with one room, 16x18 feet, inhabited by the husband, wife, and seven children. Four ounces of whisky were administered, and a four-per-cent. solution of cocain muriate was injected along the line of the proposed incision. An anesthetic, with inhaler, was ready at hand for use, in case the patient changed his mind. I must not omit, however, to state that he did not, and no anesthetic other than the whisky and cocain was used. A slightly oblique incision, four inches in length, was made, extending from the last rib at a point from 3½ to 4 inches to the left of the vertebral spines, passing a little forward as it descended to the iliac crest. The abdominal wall was carefully gone through, being 2¾ inches in thickness at this point, when, with the edges of the wound well retracted, the renal capsule and the distended pelvis bulged slightly into the wound as backward pressure was made in front on the abdomen. This was opened, when about eight or ten ounces of bloody, purulent, urinous fluid escaped. More or less thick flocculi of partially inspissated pus were found in the pelvis and calices of the kidney, but no calculi. After thoroughly washing out the pus-cavity, a liberal pledget of iodoform gauze was carried to the bottom of the wound, which was left entirely open. Dr. Wilson skillfully conducted the after-treatment, daily washing out the cavity and gradually shortening his pledget of gauze. From him I learned that only for a few days was there any urinous flow from the wound, which gradually filled from the bottom by granulation. This patient called at my office a few days since. He looks strong and well, and tells me that he is entirely free from any symptoms of urinary disease. In answer to my inquiry as to the existence of any antecedent genito-urinary or venereal disease prior to the pyelitis, he insisted on possessing a "clean bill of health from his youth up." September 10, 1896, he reported himself in excellent health.

SUBCORACOID DISLOCATION OF THE HUMERUS IN A MAN NINETY-TWO YEARS OF AGE—REDUCTION, WITH PERFECT RECOVERY.

By H. D. WALKER, M.D.,
OF FRANKLINVILLE, N. Y.

THE following case is thought worthy of reporting for two reasons; first, I am unable to find the report of any one of that age with a dislocation of the humerus, and second, I failed to reduce by Kocher's method, but easily accomplished reduction by other means. The oldest person I can find recorded with a dislocation of the humerus is eighty-six years of age. Guterbock reports one, both humeri being dislocated in an old lady by falling from her bed,[1] and Dr. H. B. Sands reports another in a lady, also aged eighty-six years.[2]

On December 23, 1894, I was called to see Mr. M. S., ninety-two years old on the seventh day of the preceding September. While emptying a pail of water he had slipped on a stone covered with ice and fallen heavily, striking on the left shoulder. He was picked up by his friends, carried into the house, and I reached him about half an hour after the accident. I found him sitting in a large rocking chair supporting his left arm with his right hand. He was very pale, and at intervals would lose consciousness from the pain and his weak condition.

On removing his clothing to the waist and examining him, I noticed that the left arm was abducted from the body about thirty degrees. There was an abrasion of the skin on the left shoulder at the upper posterior and outer part, showing plainly where the force of the fall was received. On placing the hand on the opposite shoulder it was impossible to bring the elbow down to the chest. The acromion process was prominent, and on rotating the arm the head of the humerus could be plainly seen and felt beneath the coracoid. After giving him a glass of hot whisky, I laid him on his back on a lounge, and, with an assistant to hold down the opposite shoulder, proceeded to reduce the dislocation by Kocher's method, as modified by Dr. C. A. Powers.

Four times I faithfully tried to reduce the bone in this way, but failed. In performing the second movement, *i.e.*, rotating the arm outward, so much resistance was met that it was not fully rotated, the patient exclaiming each time that I would break his arm. I did not deem it prudent, in his condition, to give an anesthetic, moreover, I have always succeeded in reducing a dislocation of the humerus without one. After a short rest, I placed a towel through the axilla and directed an assistant to take hold of the hand and make moderate extension, first, directly downward and forward, then gradually across the body to the right.

[1] MEDICAL NEWS, vol. xlvii, page 541.
[2] *Med. Record*, vol. xix, page 45.

While the extension was being made in this way I drew upward and outward on the towel, when the head was felt distinctly as it slipped back into place. This is the first time I have failed to reduce a subcoracoid dislocation by Kocher's method, and it may be well to inquire why I did not succeed. I attribute the failure to a lack of rotating the arm sufficiently outward, being fearful, on account of the age of the patient, the great resistance met, and his cries that I would break his arm, that fracture would actually occur. What was the cause of the uncommon resistance met with on rotating the arm outward? I am of the opinion it was due to degeneration of the muscles and ligaments about the joint, consequent upon old age, so they would not permit full rotation of the arm outward. I notice there are contractions of the palmar fascia in both his hands, also a want of freedom of motion about the right shoulder and the joints generally, such as we usually find in old persons. At the present time, about one and a half years after the injury, I find the arm in as perfect a condition as the right one.

MEDICAL PROGRESS.

Celluloid Bandages.—Landerer and Kirsch, (*Centralblatt f. Chirurgie*, 1896, No. 29) have experimented with celluloid as a substitute for plaster of Paris in bandages. The weight of such a bandage is less than one-fourth that of a plaster-of-Paris one and less than half that of one stiffened with water-glass. It is said to be not very expensive. According to the authors a jacket costs in Germany about 5 marks ($1.25), which is no real objection to its use when one considers that, if well made, it will last for months, and presents the further advantage of a smooth surface, readily cleaned, and is impervious to urine and other discharges.

Its application is as follows:

The sheet celluloid is cut into small pieces and dissolved in a close-stoppered bottle in acetone, enough of the fluid being used to rise four times as high in the bottle as the celluloid. This solution of celluloid is rubbed into each layer of the gauze or crinolin bandage or jacket, an ordinary kid glove being worn for the purpose, as the celluloid otherwise dries on the skin, and can only be washed off by acetone. For a jacket at least ten layers are necessary; for a bandage from four to six layers, according to the strength required. The outer layer is smeared with a coating of the celluloid, which forms, when dry, a highly polished surface. It takes three or four hours for a celluloid bandage to dry. That is considerably longer than is the case if plaster-of-Paris is used. In order to permit of ventilation, small holes may be punctured in the jacket wherever necessary.

Arsenical Paralysis.—Comby in the *Gazette Médicale de Paris*, July 4, 1896, mentions the case of a girl aged seven, whom he treated for chorea by the administration of arsenic, commencing with one-seventh grain and increasing up to one-half grain of arsenious acid. In eleven days she received nearly four grains (235 mgm.) of arsenious acid. There were no choreic movements after the fifth day. On the sixth day gastric symptoms developed, and continued some time. On the twenty-sixth day the patient left the hospital completely cured. Four weeks later she was attacked by paraplegia in the legs, followed some days later by loss of power of the muscles of the trunk, arms, and sphincters. Electrical reaction was absent. Meantime the patient, who had first entered the hospital pale and thin, had become stout and rosy-cheeked. Under strychnin, electricity, and sulphur baths there was complete recovery in about five weeks. Comby considers that the nerves were not affected by the poison, but that the patient suffered from arsenical myelitis.

Instrument for Injecting Artificial Serum.—Tolédano (*Journal de Médecine de Paris*, June 28, 1896) has devised a simple and practical instrument for the injection of artificial serum. It consists of a stout bottle, which holds the fluid to be injected. Through a rubber cork two glass tubes enter the bottle. Connected with one is a hand-bulb. The other one, which reaches nearly to the bottom of the bottle, is connected with the injecting needle. By means of the bulb air is pumped into the bottle and the serum is forced out. A chain over the cork keeps it in position.

Treatment of Ocular Traumatisms.—Trousseau (*Gazette Hebdom. de Méd. et Chir.*, June 14, 1896) gives as general rules in injuries of the eye: (1) Render aseptic the eye and conjunctiva. (2) Cover it with a dry aseptic dressing.

The former is best accomplished by free lavage with a warm bichlorid of mercury solution 1–4000. If free from alcohol and filtered, this solution cannot possibly do any harm. With the patient in a horizontal position, the lids are held apart with one hand while the solution is allowed to trickle into every corner of the eye from a mop of absorbent cotton. When thoroughly cleansed, the eye is covered with a dry, sterile dressing and a starch bandage.

Foreign bodies, if superficial, should be removed under cocain. Wounds of the conjunctiva are to be stitched with the finest catgut or silk. Wounds of the ciliary circle are dangerous, and should not be touched. Small wounds of the sclerotic heal readily; larger ones should be closed by a conjunctival flap. The author speaks against hasty enucleation, meantime watching carefully the other eye for sympathetic ophthalmia.

Apparent Recurrences of Malignant Tumors.—Gade (*Deut. med. Wochenschrift*, July 2. 1896) mentions a pseudo-recurrence of a malignant tumor in the scar left by its operation, which may very likely have caused anxiety to others. In two instances in his practice a rapidly growing hard nodule in the cicatrix of a recent operation led the operator to suspect malignancy. The nodules were removed, and upon microscopical examination they were found to be composed of fibrous and granulation tissue surrounding a few cotton fibers. This possibility of including in a wound aseptic threads of cotton is an increased one, since the use of dry-gauze sponges has become general.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

TREATMENT BY ERYSIPELAS TOXIN.

IN an article published in the *American Journal of the Medical Sciences*, September, 1896, Coley reviews the literature of the treatment of malignant tumors by injection of the toxic products of erysipelas cocci and prodigiosus bacilli, and gives details of the most instructive cases treated by himself and several other surgeons.

Recognizing the caution with which reported cures of malignant tumors have ever been received, the author has taken pains to avoid error in diagnosis, and has confirmed in almost every instance the clinical diagnosis by a microscopical one. Several microphotographs and photographs of patients before and after treatment, are reproduced. In all, 168 patients were treated by him, 94 of whom were suffering from sarcoma, 63 from epithelioma or carcinoma, and 10 from tumors, the character of which, though apparently malignant, was not absolutely determined. A few non-malignant cases were also treated.

In thirteen of Coley's patients, and ten of other surgeons, the tumors entirely disappeared. In a few instances there was a recurrence in a few weeks or months, but in the large majority no recurrence had manifested itself at the time of report, though the author does not claim that these patients are permanently cured, and owing to the uncertainty of results, he advocates this treatment only in inoperable cases. The longest elapsed time without recurrence is now over four years, the living cultures having been employed in that case.

With three exceptions, all of the tumors which disappeared under the injection of the toxins, were sarcomata. To set these twenty cases all aside as worthless, on account of a possible error of diagnosis, is to say that some half dozen of our most skilled pathologists and three times as many surgeons do not know a sarcoma when they see it; and the same sort of sweeping generalization would have to be applied to the results obtained by operation on tumors of this class. Welch, in discussing this point before the Johns Hopkins Medical Society, April 6, 1896, said that some pathologists are inclined to rank certain kinds of sarcomata among the infectious, rather than the genuine, tumors; but that this applies to the lymphoid rather than the spindle-celled sarcomata, and the fact that the best results, after injection, have been obtained in the spindle-celled tumors (fourteen injected, seven cured), is especially strong evidence of the specific curative power of the toxins.

Just what the underlying principle is, or how wide its application, Coley himself is not prepared to say. In many cases, the effect of the toxins was shown for a time by a decrease in the size of the tumor, an improvement which was, unfortunately, only temporary. In other cases it was apparent that the general condition of the patient could not stand the depressing effects of the injections in sufficient quantity or for a sufficient length of time to destroy the malignant neoplasm.

Coley has had better success with this treatment than the other surgeons who have tried it. More than one-half of all the sarcomata which came under his treatment showed at least a temporary decrease in size; and of the fourteen cases of spindle-celled sarcoma, seven, or just one-half, disappeared and have not returned. This is the type of sarcoma which responds most easily to the treatment. This favorable showing is doubt-

less partly due to the zealous continuance of treatment under conditions which would ordinarily be called hopeless, but still more, perhaps, to the fact that the toxins employed by him were all from fatal cases of erysipelas, and were proved to be possessed of a great degree of virulence. For clinical and experimental testimony agree that there is the greatest variation in the intensity of different cultures of the same bacteria, as has been strikingly illustrated—for example, in the experimentation of the New York Health Board in the production of diphtheria antitoxin.

Without for a moment sharing the illusory hopes, which every new remedy creates, the conclusion is certainly warranted that in the use of these toxins, we have a means of attack upon malignant growths, especially efficacious against certain forms of sarcomata, but whose influence extends to a certain degree to almost all of the varieties of malignant tumors, and it is not unreasonable to expect that a further experience will so extend that influence as to save many victims of cancer, whose disease is beyond the reach of the knife.

FAKE SCIENCE.

Some months ago we had occasion to speak under "The Color of Sin" of the debt of gratitude under which the secular press was constantly placing scientific medicine, by heralding medical discoveries so far in advance of actual fact and reasonable probability that the medical press seemed but laggards in the march of progress. At that time it had discovered one Elmer Gates, of Washington, D. C., who had discovered that the reaction of the perspiration, when treated by certain reagents, gave certain colors, which were indicative of the emotions under which the individual was laboring, and especially that the pink reaction was indicative of conscious guilt—the color of sin. More recently this same Gates is represented as advancing still farther into the illusory realms of biology and psychology and announcing as scientific fact the visionary mysteries of a morbid imagination.

He has been able to train animals and human beings in such a way that he causes the development of new ganglion-cells in the cortex of the brain. He purports to be able to utilize such knowledge for pedagogical purposes, and we are informed that not only his own child, but the children of others are having new ganglion-cells developed in their cortices according to the method which he has discovered.

What we know of him and of his experiments does not inspire us with confidence in his results. That he is *unofficially* attached to the Smithsonian Institute and that he has a laboratory in Washington, which is supported by the wife of a California senator, would seem to be true. Whether or not his results represent the labor of twenty years (as he maintains they do) is not germane to the subject. He began the publication of his claims by an article in the *Monist*, which was followed by others in the *Metaphysical Magazine.* In these articles, not only was the description of methods entirely insufficient, but there was a betrayal of ignorance of the nature of the animals on which he experimented. Although he has been offered the pages of *Science* for an exposition of his experiments, Gates still seems to find a syndicate article in the Sunday edition of the great dailies the most satisfactory medium for the enunciation of his views.

During the past winter he gave a lecture before the Educational Club in Philadelphia and another before the School of Industrial Art, which he thought would be a fitting place for the establishment of a great laboratory for the genesis and growth of ganglion-cells. He visited the histological and psychological laboratories of the University of Pennsylvania, and even ran his eye over the Pepper clinical laboratory, which he thought might be a possible field for his great work. He is the Keely motorman in physiological psychology. His addresses in Philadelphia contained nothing that he had not said before; as a mission for the revelation of his methods, it was a failure, and he returned to that favorite abode of pseudo-science in which he lives, without having fulfilled any of his promises.

The newly discovered stain, of which he speaks so much, is as indicative of charlatancy as is the rabbit-foot of the negro hoodoo. He calls it iodate of rhodopsin—a substance which he himself considers mysterious in its constitution and

action, but which to us seems the essence of simplicity. It belongs to that class of which bicarbonate of mucilage is the type.

There are not wanting other stigmata of the charlatan, such as the boundless promise of regeneration, which he extends to the human race, if they will but follow his method of cell-cultivation. He believes that criminals and the children of criminals can be swayed into the paths of righteousness by filling their brains with good memory-images, and thereby allowing evil memory-images to atrophy. We shall say nothing about the apparatus that he has invented for supplying oxygen to the atmosphere of houses, which shall stimulate our intellectual faculties and improve our emotional and moral natures, except to remark that if he has been experimenting with the apparatus in his own dwelling, there is no inducement to give it a trial.

If Dr. Gates is not the humbug that these methods and claims show him to be, if he has anything in his six laboratories of biological, physiological, and psychological research, we call upon him to disclose his methods so that the cause of science may not be degraded by the manners of a public trickster.

ECHOES AND NEWS.

Bone-marrow.—Parisian restaurants are serving bone-marrow, raw, on slices of bread, for its tonic effect.

Seven at a Birth.—From Dopat, Germany, Dr. Dietrich Barfuth reports a case of seven children at one birth.

To Inject Courage.—A French doctor claims to be able to inject courage into men by means of a mixture of sea-water and phenic acid.

Beriberi at Dublin.—Another outbreak of beriberi has occurred at the Richmond Lunatic Asylum, Dublin, about twenty inmates having been attacked.

The Murphy Button.—At a recent meeting of the Chicago Gynecological Society, Dr. L. L. McArthur reported three fatal cases following the use of the Murphy Button.

Absorption of Medicines.—From experiments recently made by Bersonon, weak solutions of alcohol and sugar are preferable to gums or starches as vehicles for hastening the absorption of a drug.

Vaccination in Afghanistan.—The Amir of Afghanistan has given orders for the introduction of vaccination by calf-lymph. Smallpox destroys one-fifth of the infant population every time an epidemic appears in Cabul.

Dartmouth Medical College.—Dr. William Thayer Smith, who has been professor of physiology for a number of years, has been appointed Dean of Dartmouth Medical College, to succeed the late Carleton P. Frost. Professor Gilman P. Frost has been appointed the secretary and treasurer.

Heavy Damages for Sewer-poisoning.—For maintaining a ventilating-shaft in a chimney of a house belonging to a gentleman whose death was alleged to have been caused thereby, the King's Norton Rural District Council was mulcted in the sum of £3500 at the Birmingham Summer Assizes.

Diphtheria Antitoxin in Austria.—Out of 1100 cases of diphtheria treated with antitoxin in Austria, 970 recovered. When this remedy was employed in the first two days of the sickness, the percentage of deaths was only 6.7. Of 318 cases of preventive inoculation, only 20 were attacked by the disease, and these in a mild form.

Leprosy at Bellevue.—A German baker, who had been sleeping at the city lodging house on the Bellevue Hospital grounds, was discovered to be suffering from leprosy. He was sent to join the leper colony of two negroes and two Chinamen, on North Brother's Island. He contracted the disease in Brazil.

A Crusade Against Noises.—The Health Commissioner of Milwaukee is the initiator of a much-needed crusade. His proposition is that a certain amount of nerve-energy is required to resist noises, and when these are abnormally loud they make a large drain upon the nervous system. He therefore intends, as far as he may, to stop all unnecessary noises.

A Protozoan a Cause of Cancer.—A parasitic ameboid rhizopod, described as *Leydenia gemmipara*, has been found in the fluid taken from patients suffering from cancer of the stomach, and is believed to have a causal relation to that disease. The discovery of this new protozoan was made at Professor von Leyden's laboratory at the University Hospital, Berlin.

Two Typhoid Outbreaks.—Professor Sedgwick, of the Massachusetts Institute of Technology, has been investigating the recent outbreak of typhoid fever at Cambridge, which, at one time, threatened an epidemic. He has traced every case to the milk-supply, there being a case of typhoid in the family of the milkman. The New Haven outbreak has resulted in the drafting of an ordinance providing for the licensing of milk-vendors and an inspection of the milk and of its sources of supply.

The Plague of St. Kilda.—Between 1860 and 1865, out of 125 children born on the island of St. Kilda, 84 died within the first fourteen days of life. Unsuccessful attempts were made at various times to discover the morbid agent, and the natives finally regarded the disease as a dispensation of Providence. In 1892 a Glasgow physician recommended an iodoform dressing for the cord, with the result that there has not been a single death among the infants. The mysterious malady was tetanus neonatorum.

The Effect of High Altitudes on the Blood-corpuscles.—The blood contains a larger number of corpuscles in the mountains than on the plains, and this increase occurs at very moderate elevations. Dr. Arnould points out, in the *Revue d'Hygiene*, that diminished barometric pressure is only one of a series of influences exerted by residence at a high altitude, among which must be mentioned the purity, the dryness, and the comparative low temperature of the air of the mountains, together with the intense solar radiation in these parts.

Gould's Dictionary of Medicine.—The Educational Number of the *Lancet* commends the above book as one of the best dictionaries of its kind that it has ever seen. "It should have a place in the library of every medical man." The list of books recommended for the consideration and choice of medical students occupies several pages, but if our examination of that list has not been too cursory, there is no other English-made lexicon among them. Dr. Gould is to be congratulated upon such spontaneous and unusual commendation.

New York State Medical Society.—The Business Committee of the Medical Society of the State of New York, consisting of the following members, has been appointed: Dr. Seneca B. Powell, 12 West Fortieth street, New York, chairman; Dr. Willis G. Macdonald, 27 Eagle street, Albany; Dr. Ernest Wende, 471 Delaware avenue, Buffalo. Communications regarding papers to be presented at the next meeting of the Society, to be held in Albany, January 26–28 next, may be addressed to them or to the President. Dr. James D. Spencer, of Watertown.

A Professional Skeptic.—Dr. Schweninger, Bismarck's physician, delivered an address at the Berlin exhibition on "Medical Men and Medical Practice." He holds that medical science consists essentially in the study of one's self, in the avoidance of disease as far as is humanly possible, and, when it does come, in awaiting its departure with the greatest possible amount of resignation. He advised haste in "making use of each new remedy while it still cures." The medical man of the present day is, in his opinion, surgeon, bacteriologist, electrician, anatomist, microscopist, physicist, or physiologist, but is very little of the physician. He holds most of the new discoveries of medical science to be either useless *ab origine*, or old remedies long since tried and abandoned. The corset in woman and the silk hat in man, he declared, were the two great sources of ill health.

Libraries of Three Thousand Volumes.—Mr. G. Hedeler of Leipzig writes as follows, regarding his laborious work of listing the important private libraries of all countries, whether general, medical, or special: "The 'List of Public Libraries of all Countries,' compiled by Royal Librarian Richter, has been completed by me some time ago, and I now propose to follow it by a similar 'List of Important Private Libraries.' In order to be able to apply for particulars to the owners of private libraries it is first necessary for me to ascertain their names, and for this purpose to be favored with kind assistance from any quarter. Would you perhaps have the great goodness to note for me the names and addresses of any of your acquaintances whose libraries you may estimate as exceeding three thousand volumes, or smaller if devoted to some specialty." He deserves the help of all good Americans who have given special attention and care to the collection of medical libraries.

The English Department of Sei-i-Quai.—The *Chemist and Druggist* pokes fun at the pidgin-English of a newly appointed Japanese editor, saying: *Sei-i-Quai* is a Japanese journal which is printed both in the vernacular and in English. The editorship of the English section of the journal has recently been assumed by Dr. Kimura, who makes an announcement to that effect in the paper, and then starts off by describing Dr. Kitasato's experiments with the bacillus of the Chinese plague in this way: "The pest-bacillus is of rod-shape whose both extremities stain deeper than the middle part with anilin pigment, and has a capsule; its shape resembles the bacillus of chicken cholera. The pest-bacillus is differ from all other bacilli of infectious diseases, being inoculated by three channels—by lungs, stomach, and by hypodermic injection. In the blood of the patient in convalescent state, after decline of fever, abundant of the pest-bacilli still present; and therefore, immunity to the disease can easily be secured, by a certain method which Dr. K. is investigating at present." Dr. Kimura's assumption of the editorship of the English section of the paper reminds us of the old *Punch* joke about the amateur actor who asked a friend, "How did you like my assumption of the part of Hamlet?" "My dear fellow," came the reply, "I assure you it was the greatest piece of assumption I ever saw in my life."

Shorthand in Medicine.—Those practitioners, says the *London Lancet*, September 5th, who wish to take notes of cases or to record facts in their note books, which have been gleaned in readings or by observation, will find in shorthand a means not only to greatly economize time, but will change the laborious task of recording notes in long-hand into a work of pleasure. Its use by the student is of equal value. In the lecture theater, in the demonstration rooms, by the bedside, in the out-patients' department, and in a variety of other ways, the use of shorthand will enable him to record his experience in less time and in a more convenient manner than by the use of long-hand, and, in addition, the information will be ready to his hand when wanted. There is also another advantage, and this not a small one, which the study of phonography confers. Rightly used it has an educational value of its own. In acquiring any kind of knowledge two of the most important habits to develop are attention and method, and both are developed and strengthened by an intelligent use of phonography. Efforts are being made to induce the General Medical Council to recognize shorthand as an extra optional subject at the preliminary examination, and petitions, with that object in view, have been presented to the Council. Whether the desired object will be attained or not we strongly advise all medical students, if they can find the necessary time, to learn shorthand.

The Water Supply of Brooklyn.—The Department of City Works of Brooklyn has received from Professor A. R. Leeds, of Stevens Technological Institute, a preliminary report of his investigation as to the causation and prevention of the malodorous condition of the Ridgewood water supply. All the specimens in themselves are colorless. What has been termed their color is, properly speaking, their turbidity, and this turbidity is due to foreign suspended matter in the form of fine whitish particles, and in the form also (this latter condition being much the greater in bulk) of flocculent whitish-yellow filaments or strings. Dr. Leeds explains that the turbidity is due to two different kinds of foreign matter, the greater part settling quickly as coherent strings to the bottom of the jar, the smaller part remaining permanently suspended in the water and giving it a permanent opalescence. This opalescence is similar in character to that of the water of the driven wells used by neighboring communities on Long Island for their water supply, after this water has lost its perfectly colorless, limpid appearance on standing for some time exposed to the air. The opalescence contains nothing that is capable of identification and study under the microscope. From experiments that could not be detailed here, it appears that the principles which impart the odor are volatile amides belonging to the aromatic series of organic compounds. Those which impart the taste are amides, also, of closely related composition, but of less volatility and probably of less solubility. From these data it will be seen that the free and albuminoid ammonias are present in very small amounts in most of the samples. But the nitrates are present in enormous quantities, making the lowest ratio in which the mineral nitrogen is greater than the organic nitrogen 8, and the highest 128. In connection with the small amount of albuminoid ammonia, it should be brought prominently into view that in its normal and usual condition, the Brooklyn water contains this constituent in exceedingly minute quantities. In fact, the Brooklyn water, in its ordinary state, should be ranked as first in regard to purity of all of the water supplies of our principal cities. This encomium is made deliberately and advisedly, and is based upon a comparison of the analyses, spread over twenty-six years, of the water supplies of all the important towns in this country and Canada. But, in its present condition, it has been a peculiarly favorable habitat for the multiplication and growth of certain vegetable organisms, which, in turn, have secreted the products that have rendered the water turbid, and, in course of their decomposition, have originated the foul tastes and odors. The absolute quantity of decomposed material in the water, instead of being large, is very small, and the taste and odor are due to an excessively minute quantity of the amide substances. The objectionable odor, color, and taste of the water are due to vegetable organisms coming from the supply, which produce their objectionable effects after the water enters the distributing system. There is no danger in the use of the water at present.

The Relative Strengths of the Antidiphtheritic Serums.—The following is a portion of a letter to the *London Lancet*, by Dr. Hermann M. Biggs of New York, on the above subject; the date of the letter is August 13th and the date of the journal in which it appears is August 22:

"It has been a source of surprise to us in America that so little attention has been given to this phase of the subject in Great Britain, and to the necessity for the statement on every phial of antitoxin not simply of the dose of the serum, but of the antitoxin value of each cubic centimeter of the contents. These matters, as you have pointed out, are of preëminent importance.

"In January, 1895, on the motion of Professor T. Mitchell Prudden and myself, the New York City Health Board adopted an amendment to the Sanitary Code requiring that all preparations of diphtheria antitoxic serum exposed or offered for sale in New York City should bear labels showing the strength in antitoxin of the contents as measured by some generally recognized standard of value. The result of this action has been that nowhere in America, so far as I know, have preparations of antitoxin been sold which do not conform to this requirement, although the action of the New York Health Department in adopting regulations regarding the matter has not been generally followed. Tests of the preparations of antitoxic serum on sale are made in various parts of the United States by the different sanitary authorities to determine their conformity to the strength given on their labels, notably by the Massachusetts State Board of Health, and the New York Health Department. I have been much surprised by the low grade of the preparations used in Great Britain. As will be seen by the enclosed circular, so long ago as February, 1896, the New York Health Board discontinued the preparation and use of the 'No. 1' and 'No. 2' grades of antitoxin (Behring's standard), and added to their list three higher grades, Nos. 4, 5, and 6, containing, respectively, 200, 300, and 400 units of antitoxin (Behring's standard) in each cubic centimeter. The whole difficulty in the production of high-grade preparations of antitoxin depends upon the production of high-grade toxic solutions, and the latter were rendered easily possible by the method worked out in the New York Health Department Laboratories by Dr. Park and Dr. Williams, and published in the first number of the *Journal of Experimental Medicine*, edited by Professor William H. Welch of Johns Hopkins University, Baltimore. I am informed that the results obtained in New York have been confirmed by M. Martin of the Pasteur Institute in Paris, and that Kossell of the Institute for Infectious Diseases in Berlin, has recently published an article (which I have not seen) describing essentially the same method, not mentioning, however, the work of Dr. Park and Dr. Williams. The method used in New York has been generally followed in the United States, and high-grade preparations are everywhere to be obtained. Within the last two months another preparation, No. 7, has been added to the list, furnished by the New York Health Department. This contains 500 units in each cubic centimeter.

"It seems unnecessary to refer to the great advantages derived from the use of preparations of antitoxin in which the dose is only three or five cubic centimeters instead of ten, twenty, or thirty cubic centimeters."

CORRESPONDENCE.

SPONGE-GRAFTING IN THE ORBIT.

To the Editor of THE MEDICAL NEWS:

DEAR SIR: In your issue of June 27, 1896, in an article entitled "Sponge-grafting in the Orbit for Support of Artificial Eye," Dr. E. Oliver Belt says: "I cannot find, in all the medical literature in the library of the Surgeon-General's office any mention of sponge being used as I have suggested and tried."

In *Gaillard's Medical Journal* for May, 1889, I published an article entitled, "On the Formation of an Artificial Vitreous Body." In this article I detailed the results of a number of experiments made on rabbits by grafting sponge and cotton in the scleral cavity and sponge into the capsule of Tenon. In the recent meeting of the American Medical Association in Atlanta I presented a paper on the formation of an artificial vitreous body, which, while it did not refer to the orbit, but rather to sclera, might have called Dr. Belt's attention to this subject.

In my original article I detailed my experiment by which I planted sponge in the capsule of Tenon. The rabbit did well until the second month after the operation, when it was observed that the sponge had broken through the line of sutures and "presented a white, honeycombed appearance." "When removed, the sponge seemed to be about twice the size of the eyeball. The contents of the orbit seemed to have shrunk away from it, for the cavity seemed to be quite roomy."

In view of this unfortunate result in rabbits, I have never had the temerity to graft sponge in the orbital cavity of man. Dr. Belt states he has performed this operation in five cases "with fairly good results in all, but union of the conjunctiva has not been firm enough to prevent some of the stitches from breaking or cutting out and the wound gaping."

It would be interesting to know the condition of the socket of these eyes after a year or two have elapsed.

I do not believe the operation will stand the test of time.

I enclose the letter of Dr. Belt to me, which I publish by his permission.

Very respectfully,

J. HERBERT CLAIBORNE, M.D.

NEW YORK,
September 15, 1896.

DEAR DR. CLAIBORNE: Your letter calling my attention to your article in *Gaillard's Medical Journal* about your experiments on rabbits, in which you tried sponge-grafting in the orbit, was received a few days ago. I am very glad you wrote to me about it, as we always want the facts in regard to priority of such investigations, and I believe in giving credit to whom credit is due, although it was also original with myself, as I had never heard of sponge-grafting in the orbit being done, either on animal or man, before doing it myself, and I suppose still that I was the first to try it in the human orbit. Since receiving your letter I have found your article in *Gaillard's Medical Journal* for May, 1889. At that time the *Journal* was not indexed as well as now, and, without your name and the title of the paper, I should have had much trouble in finding it, which accounts for its being overlooked when I searched the records at the Library of the Surgeon-general's office to see if anything of the kind had been done previously. I found the experiment much more satisfactory in man than in the rabbit, which I tried it upon, and hope you will give it a trial.

Yours very truly,

E. OLIVER BELT.

WASHINGTON, D. C.,
August 31, 1896.

SPECIAL ARTICLE.

ADDRESS TO MEDICAL GRADUATES.[1]

BY CH. WARDELL STILES, A.M., PH.D.,
ZOOLOGIST U. S. BUREAU OF ANIMAL INDUSTRY; CORRESPONDENT ETRANGER DE L'ACADEMIE DE MEDECINE (PARIS).

IT may possibly seem strange to you that the Faculty has selected a zoologist to give the parting word of advice to a medical class. Fifty or even twenty-five years ago this would have been looked upon as almost an act of high treason to the medical fraternity; but in recent decades there have been great changes in medical circles, and one of the most logical has been the recognition of the fact that no sharp line can be drawn between doctors of medicine on the one hand, and doctors of science or philosophy on the other; or in other words, between men trained in applied science and those trained in abstract science. My addressing you is, therefore, fully in harmony with the changes our respective professions have recently undergone, and I cannot refrain from expressing my satisfaction at having the opportunity of speaking to you upon this particular occasion, for I feel rather as if I belonged to the Class of '96, since I entered the Georgetown Faculty the same year you became members of the student body.

I intimated that there was no dividing line between the abstract and the applied sciences. The student of medicine is looking more and more to the chemist, the physicist, the botanist, and the zoologist for aid in solving his medical problems. To a chemist you owe the most radical change in thought and practice, which your profession has ever undergone, though it may not be known to you that this man, who has done more to lessen physical suffering in man and animals than any other person of this century, was not permitted by the laws of France to practise medicine. The noted Pasteur clinic of Paris, while virtually under the direction of that ideal man of science, was not under his control in the eyes of the law, and he was obliged to engage as his assistant a doctor of medicine, who should assume the legal responsibility.

But your relations to the chemist were not due to Pasteur alone. Chemistry has taught you nearly all you know about toxicology, and much that you know about physiology; it is the basis of your therapeutics, and if we ever arrive at a solution of that riddle known as "immunity," it will be largely through our friends the chemists.

To the physicist you are indebted for the use of elec-

[1] Delivered before the graduating class of the Medical Department of Georgetown University, Washington, D. C., May, 1896.

tricity, the explanation of the normal and many of the abnormal postures of the body, the principles upon which your instruments are constructed, the explanation of certain conditions in which gravity plays a more important rôle than gravidity, and for the recent development of the X-ray, which promises so much that one is almost afraid to speculate in regard to its manifold applications.

To the botanist you are indebted for data concerning medicinal plants, as well as for very important researches in bacteriology; and it is my firm conviction that if bacteriology ever emerges from its present chaotic systematic condition, it will largely be through the direct or indirect influence of botany, for the pathologist without special training in taxonomy is no more capable of reducing the bacteria to a natural classification than is the botanist without special training in pathology capable of correctly interpreting pathological histology.

To the zoologist you owe the transformation of anatomy from a descriptive into an explanatory science. He has already solved the riddles of many of the rudimentary organs of the human body. You are no longer taught that the pineal gland of the brain is an unexplained organ, possibly the seat of the soul, but you are told that it represents a rudimentary third eye, which has been traced through a long series of animals until found developed to such an extent in certain reptiles that it is probably capable of perception of lights and shadows, while the paleontologist has here come to our aid and shown that in certain fossil reptiles this organ must have been a comparatively well-developed interparietal eye. You no longer learn a minute description of the *plica semilunaris* and then wonder what it is, for you are told that it is a third eyelid, very rudimentary in most human races, slightly better developed in the Malay, while it is well-developed and functional in birds and frogs. Your present knowledge of embryology, histology, the origin of the individual and of the race, and even the *raison d'être* of that fashionable death-trap, the vermiform appendix, you owe directly to zoology. This science has further given you certain animals, such as sponges and the Spanish fly, to be used in your practice; it has given you scientific data concerning the poisonous snakes, which cause so many deaths, and the animal parasites, with names often much longer than the organisms themselves; it has shown you means by which certain diseases may be prevented. In fact, your profession is, in reality, pathological zoology.

Permit me briefly to call your attention to two ways in which you may repay, in part, what you have borrowed from zoology. As practising physicians you will occasionally be able to collect material which will be of use to zoologists. Too frequently the practitioner allows valuable specimens, such as young embryos, deceased monstrosities, and parasites to be cremated, buried, or thrown away, instead of saving them for scientific study. You should remember that no embryo is so young, no monstrosity or parasite so common that it is not of some use to the scientist. How often have physicians said to me: "I would have saved the specimen, had I thought it could be of use to you!" Gentlemen, let me tell you again, as I have already told you in the lecture-room, all such specimens should be saved for scientific purposes. If you meet with objection on the part of the family, which, fortunately, rarely happens among the more educated classes, you can at least make careful observations and notes upon the case. And this leads me to the first suggestions in the way of advice, *i.e.*, observe carefully, and take notes of your observations. These notes cannot be too detailed, especially at first; and probably, for a year or so after graduation, most of you will have ample time to take rather copious notes upon all you observe.
